THORACIC SURGERY.

BY S. J. MELTZER, M.D., LL.D.*

NEW YORK.

WE are on the point of starting a new National Medical Society. It is a part of the duties of the presiding officer to state at such an occasion the aims and scope of the society and the reasons for its creation. But the present officer feels that first of all he owes a duty to the members and to himself to tell something of the circumstances which gradually brought him into the Presidential Chair of an Association for Thoracic Surgery. The little story is perhaps worth telling. When about forty years ago, I began my very modest career as an experimental investigator in the domain of medicine, I had no reason to anticipate that one day the honor would be conferred upon me to preside over a body of progressive physicians who wished to discuss particularly the surgery of the chest. I began my career by introducing stomach tubes into my esophagus. There seems to be no clear connection between this heroic act and thoracic surgery. But by good will a series of loose events can be detected and forged together into a chain capable of connecting both end points. My studies of the physiology of deglutition ripened in me the general conception that the phenomenon of inhibition is an important factor in all functions of the animal body. This conception of the mechanism of life never left me. It was a working factor in my studies of the respiratory function. When later, about twenty years ago, I came across the depressing action of magnesium salts, it then occurred to me that the magnesium is perhaps the representative of inhibition in the animal body. This view became a working hypothesis in our numerous investigations of the action of magnesium salts. Further on, in the attempts to utilize our new knowledge for therapeutic purposes, we soon realized that magnesium may inhibit the function of respiration. Now magnesium salts leave the circulation quite rapidly, and any danger from an inhibition of respiration could be met by temporary artificial respiration. But there were no satisfactory methods of artificial respiration which could be readily used in such emergency cases. The manual methods were entirely insufficient for our purpose. In our search for efficient methods we developed, Auer and I, the method of intratracheal insufflation. You probably remember the little battle between differential pressure and intratracheal insufflation. It occurred only eight years ago; but it seems now like history. When I presented my paper on intratracheal insufflation at the New York Academy of Medicine, my views were opposed, in the interest of conservatism in surgery, by three able surgeons. Now, these same surgeons are among the principal founders of the American Association for Thoracic Surgery, and my being the first presiding officer of the Association is due exclusively to their generous spirit and not to any merits of mine. This is my little story of how the introduction of a stomach tube carried a mere medical man into the presidential chair of a National Surgical Association.

Now I am coming to the performance of my duties, namely, to tell of the aims and scope of the Association and to give the reasons for its creation. Of course this could have been done better by the real founder of the association, by the member who is going to give us a review of the evolution of thoracic surgery in the past fourteen years and who by right should have been the occupant of this chair. But he willed it otherwise. As the name indicates, the chief aims of the Association are the advancement of the knowledge of and skill in thoracic surgery. It is expected that a greater progress will be attained in this line of medical research by focusing the attention of a group of practical surgeons to the thoracic cavity, by working together with physicians and surgeons, who are interested in special diseases of the thoracic cavity and its adjoining regions, and by working together with various experimental investigators in these fields.

Is it necessary to single out the thoracic cavity for special activities and is the thoracic cavity not part and parcel of the domain of all general surgeons? In looking for light on this question I did not have to go far to discover the fact that the thoracic cavity apparently has no special attraction for most of our leading surgeons. I shall cite only two illustrative instances. The program of the American Medical Association reflects the medical and surgical activities of the entire country. In looking over the program of the coming meeting, as it was published a few weeks ago in the *Journal* of the Association, I found that there were numerous papers on abdominal surgery sufficient to crowd the programs of two surgical sections with an overflow into the Section of Gastro-enterology; but there was not a single paper on thoracic surgery. Then I glanced through the volumes from the Mayo Clinic. They show us the sort of work which is done in this brilliant surgical institution. I found only two or three papers belong-

*President's Address at the meeting of the American Association for Thoracic Surgery, Chicago, June 10, 1918.

ing to the domain of thoracic surgery and these papers were written by a member of our Council while he was on the staff of the Mayo Clinic. Wonderful work is being done in this Clinic on organs below the diaphragm and above the thorax; but there is practically complete silence on intrathoracic organs, at least so far as surgery is concerned.

Does the development of thoracic surgery receive attention and support from our brilliant practical surgeons equal in extent and intensity to that bestowed upon abdominal surgey? A fairly instructive answer to our query may be obtained from the following analysis of the history of two similar incidents in abdominal and thoracic surgery. It was about the same time, about the middle of the last century, that a perityphlitic abscess (Hancock, 1848) and an abscess of the pleural cavity (empyema) (Sayre, 1842) were incised for the first time. Now let us compare the progress which followed both incidents. The opening of the perityphlitic abscess did not only lead to the removal of the appendix in acute stages of inflammation and to frequent interval operations for appendicitis—the latter meaning the exposure of the *normal* peritoneum, without trembling and with impunity; but it paved the way to the handling by the surgeon of every organ located within the abdominal cavity and to very frequent exploratory laparotomies for mere diagnostic purposes. In other words, surgeons, great and of medium size, have nowadays no hesitation whatsoever in opening the abdomen, exposing the normal peritoneum, and manipulating the abdominal organs without urgent indications for its performance and without fear of untoward results. Would the celebrated surgeons of half a century ago, who surely considered the opening of a typhlitic abscess as an heroic act, have admitted the possibility that a day will come when the normal parietal and visceral peritoneum could be exposed and manipulated with absolute impunity?

Now let us look at the progress in thoracic surgery made during the same period. It is true that one or the other surgeon pleads courageously nowadays for an exploratory thoracotomy in cases of empyema; but we must bear in mind that that which they wish to explore and manipulate is a simple or multilocular *abscess cavity* and not the normal parietal and visceral pleura. Is there a greater danger in exploration of the normal pleural cavity than the exploration of the normal peritoneal cavity? Our leading conservative surgeons seem to think so. But after the introduction of intratracheal insufflation Carrel and others have in numerous instances opened freely and simultaneously both pleural cavities for the purpose of patching the thoracic blood vessels and other operative procedures with complete impunity. Carrel and other experimental thoracic surgeons could do it, because they employed methods which, above all, insured the safety of the respiratory function. But our conservative surgeons say that for the surgical work on the thorax the new, hazardous methods of artificial respiration can be dispensed with, because the operations performed upon the thoracic cavity of human beings can be carried out under simple anesthesia without complicated methods. Here is the rub. The masters of technique, and fearless operators in the field of abdominal surgery, when they come to thoracic surgery confine their work chiefly to the abscess cavity of the pleura, which, by means of the abscess wall and the newly formed adhesions, protects the respiratory capacity of the lung in the other pleural cavity and also the remaining respiratory power of the non-collapsible part of the lung on the operated side.

Does the thoracic cavity possess features which distinguish it from other serous cavities so as to merit particular attention? Indeed, it does, and in a striking fashion. Every elementary textbook on physiology will tell you so; only the successful operations upon the abscess cavities of the thorax dim the vision of the surgeons. The opening of a normal pleural cavity causes a complete collapse and immobility of the corresponding lung. In dogs, the opening of one pleural cavity is, as a rule, sufficient to cause the death of the animal. As to human beings, I believe that no experience is available to answer this question; the opening of a pleural cavity was made, as a rule, either in diseased conditions which may have caused adhesion of some part of the lung or at least a complete isolation of the two cavities by means of a thickened mediastinum; or the opening was made under some form of artificial distention of the lung. Besides the respiratory mechanism, the thoracic cavity harbors the chief organ of circulation. An interference with the activity of this incessantly-beating organ may unexpectedly lead to danger, and even to immediate death. These serious problems confront the surgeon who has to work in the thoracic cavity, in addition to the serious features which the surgeon has to consider in dealing with all serous cavities.

I wish to emphasize here the significant fact that the additional serious problems which confront the thoracic surgeons are essentially of a *physiological* nature. Surgeons are generally well trained in *anatomy*, in technique, and in mechanical manipulations. Here there is hardly any limit to their courage and progressiveness. But when it comes to problems which have a predominant physiological aspect an undesirable form of conservatism comes to the fore.

I believe that I brought forward a sufficient number of reasons showing the desirability of knitting together a group of medical men who possess the necessary scientific preparations and the aptitude to work along lines which will help us to advance the knowledge and the skill of thoracic surgery; in other words, I gave you reasons for the creation of the Association for Thoracic Surgery. In performing my duties as the president of the association I may rest here my pleading the cause of the association, but I ask permission to add some remarks on subjects which interest me as an active worker in the problems belonging to the domain of our association.

I shall deal first with the method of intratracheal insufflation. I entertained the conviction that the right of this method to permanent citizenship in the domain of surgery has been established beyond a doubt. But in looking over the literature I came across a paper which contains a rather severe judgment against the method, rendered in a sharp, categorical manner. The paper was written by a man

who at all times is entitled to a respectful hearing. But just at present he is the man of the hour; he will be the next president of the great American Association; it was written by Dr. Bevan. It is, perhaps, fortunate for a president of such a young and small society as ours to be in the position to rub against the president of the largest national society; my discussion with him may thus get a hearing. In a paper, entiled "The Choice and Technique of the Anesthetic," published in 1915 in the *Journal of the American Medical Association* (the issue for October 16), Dr. Bevan deals among others with the intratracheal anesthesia. From his conclusions it is sufficient to quote two which leave no mistake as to his views. "The method is dangerous," he begins, and finishes up by saying that, "On the whole, therefore, intratracheal anesthesia has little place in practical surgery." On what experience are these dicta of Dr. Bevan based? I received from a most reliable source the information that no patient was operated in Dr. Bevan's clinic by the method of intratracheal insufflation. If Dr. Bevan has seen the method used elsewhere and with bad results, he should have expressly stated that fact. On what information, then, did Dr. Bevan base his categorical statement? He quotes the paper of Dr. Robinson of several years ago in which fourteen hundred cases were collected with seven deaths. It is quite strange to find that in striking contrast to Bevan's conclusions, Robinson, on the basis of his statistics and observations, proves himself in this paper to be an ardent supporter of the method. He says there, "Those of us who have managed intratracheal anesthesia during general surgical operations are universally impressed with the ideal condition which exists." Did Bevan try to analyze the seven cases of death mentioned in Robinson's paper? Well do I remember three cases. In one case the ether bottle was reversed by mistake and pure ether was driven into the lungs; in another, the nurse pushed the intratracheal tube, while being connected with the pressure apparatus, deep into the bronchus, which led, of course, to rupture of the lung. In a third case the patient was in a prone posture with the anterior part of the neck hanging over the edge of the table; the patient was not looked after, and it was discovered late that the insufflated air and ether mixture had no chance of escaping. Does Dr. Bevan believe that these gross "errors" have anything to do with the method as such? On the other hand, how does he explain the facts that men like Dr. Elsberg, who used the method in more than twelve hundred cases, and Dr. Peck, who used it in more than five hundred cases, never encountered any accidents?

Without entering into a further discussion of the validity of Dr. Bevan's dicta in this instance, I may be permitted to refer here to two instructive statements. Tuffier, who is probably as good an authority on thoracic surgery as Dr. Bevan (on invitation, he presented an extensive report on thoracic surgery before the Surgical Section of the International Congress in London in 1913) published an article* in which he says, among others, that according to his opinion, based upon personal experience with the method, intratracheal insufflation anesthesia will be in the future the only method of anesthesia for thoracic surgery.

In an article (submitted by the Section of Plastic and Oral Surgery and approved by the Surgeon General, U. S. A.) published in the *Military Surgeon* for May, 1918, the following simple statement is made: "The utility of intratracheal anesthesia for certain types of operations is well established." Perhaps I may add that in the many thousands of cases in which intratracheal ether anesthesia was used *not a single case of ether death* occurred.

There is another point which I wish to bring out here. Intratracheal insufflation is generally discussed from the point of view as a method of administering anesthesia. It is overlooked that it provides the patient during the anesthesia with a luxurious artificial respiration. *It is not generally appreciated how important this point is.* Auer and I found that ether has a curare-like action upon the endings of the motor nerves, and Githens and I found that during ether anesthesia both the diaphragm and the phrenic nerves lose some of their irritability. It is no doubt that during ether anesthesia an element of asphyxia is present. Now, this fact is very important, especially when one works in the neighborhood of the heart. When the individual receives efficient artificial respiration simultaneously with the ether anesthesia the heart may be handled with practical impunity. It is different when the respiration is insufficient; the heart often responds to each touch with a series of irregular beats which in some hearts may lead to ventricular fibrillation and a heart death.

The so-called pharyngeal method of anesthesia, of which Bevan and other surgeons are now speaking favorably, is, of course, incapable of providing efficient artificial respiration. It is different with the pharyngeal insufflation which I described about a year ago and the efficiency of which I have recently demonstrated to hundreds of military medical officers and other interesting parties. But I do not intend to dwell here on this subject.

Finally, as the president of the Association for Thoracic Surgery, I shall avail myself of the opportunity and the privilege to make one or two remarks on topics of human thoracic surgery. It seems to me that the most desirable object in thoracic surgery is the proper development of *exploratory thoracotomy* with the object of using it in the same manner and for the same purpose as exploratory laparotomies are used, that is, in the first place for making a proper diagnosis. I risk making the statement that in some conditions the exploratory incision in itself may even exert a therapeutic effect. In some instances exploratory laparotomies undoubtedly influence favorably pathological processes in the abdominal cavity. I have a theory for it; but I shall not dwell upon it now. At any rate, an exploratory thoracotomy may lead to a proper understanding as to the therapeutic measures which could be employed now or later. On the other hand. I would rather counsel conservatism in the attempts

*Tuffier (*Presse Médicale*, June 1, 1914, p. 497).

"Ces indications nous paraissent devoir être les suivantes; 1° Eile constitue, sans aucun doute, la meilleure méthode d'anesthésie et de pression positive dans la *chirurgie intratheracique*, nous pouvons dire restrictions *la méthode d'avenir*. nous l'avons utilisée dans la résection de l'œsophage thoracique et, malgré une installation rudimentaire, la fonctionnement de l'appareil et les résultats de l'anesthésie ont été parfaits."

to perform untried and unstudied methods of operation. An occasional success rapidly leads to repetitions and numerous failures, and this discredits thoracic surgery. Patient, practical, and experimental studies should be the means of paving the way to the final success in thoracic surgery.

My second suggestion is rather bold, and I am well aware that it will not be acceptable to most of you if to any. Nevertheless, I am throwing out this suggestion, looking upon it as a seed which may perhaps take root somewhere some day. I propose that large intercostal incisions should be made for the treatment of pulmonary tuberculosis. If the procedure does not interfere with the respiration, that is, if it proves that the mediastinum sufficiently protects the respiratory activities of the lung in the opposite cavity, steps should be taken to keep the incision open for a longer period. If the lung of the opposite side is also affected, the same procedure should be followed out later when the first incision is healed. The idea underlying this suggestion has nothing in common with the method of treatment by means of insufflation of nitrogen in the pleural cavity. Forlanini's method is based upon the supposition that rest will act as a curative agent. The ideal rest of the kidneys does not prevent development and progress of tuberculous processes in their parenchyma. My suggestion is stimulated by the experience of the curative effect of laparotomy upon tuberculous peritonitis; the introduction of nitrogen or oxygen into the peritoneal cavity exerts no such curative action. We should bear in mind that the treatment of tuberculous peritonitis by laparotomy owes its origin to mistaken diagnoses which were made by Spencer Wells in England and by Van De Walker in this country. In years gone by nobody would have thought of suggesting the treatment of tuberculous peritonitis by an abdominal incision, and if it had not been for the accidental errors in diagnosis, it might never have been performed. So far we do not possess a clear explanation of the nature of the therapeutic effect of the laparotomy; but there is no doubt as to the fact of the therapeutic result. Thoracotomy may exert a similar therapeutic effect. If we could only test and establish the fact of therapeutic action, the explanation of the effect may wait in thoracotomy as it has had to wait in laparotomy. I venture to throw out the further hypothesis that the moderate distentions of the partly adherent exposed lung may rather prove to be a favorable factor in the possible therapeutic action of a thoracotomy. I have my reasons for this hypothesis, but I shall not discuss them; I think I have done more than enough by venturing to make the bare statement.

I do not expect to live to see my suggestion taken seriously and tested. But, you see, a physiologist rushes in where surgeons fear to tread.

The Rockefeller Institute for Medical Research

Magnesia and Cancer.—Dubarde gives from 8 to 12 grams of white magnesia daily to all of his operative cases of cancer, his theory being that poverty of the organism in magnesia favors the development of malignancy. Remineralization would seem to be an important aspect of the problems of prophylaxis and immunity.—*La Presse Médicale.*

RELATION OF INTERNAL SECRETIONS AND FAULTY METABOLISM TO MENTAL PERVERSIONS.*

By BITTLE C. KEISTER, A.M., M.D.

ROANOKE, VA.

We are to-day facing many and divers theories on the subject of internal secretions, their effect on metabolism, and their relation to mental perversion. We are all more or less familiar with the caprice and peculiar freaks played by the ductless glands. Take, if you please, the thyroid, the thymus, the pituitary, the pineal, etc., whose physiological functions are exciting the liveliest interest thoughout the scientific world. Our foremost scientists are to-day puzzling their brains over these apparently insignificant organs.

The most definite clue to the action of internal secretions has been obtained with the thyroid. Recent experimental work on this gland makes it necessary to distinguish between the thyroid and the parathyroid tissue. The thyroid proper consists of two oval bodies located on the sides of the trachea at its junction with the larnyx. These have no ducts, and are composed of vesicles of various sizes, which are lined by a single layer of cuboidal epithelium, and contain in their interior a material known as colloid. This material is formed within the lining of epithelial cells, and when the vesicles rupture it is discharged into the surrounding lymphatics. The nature of this colloid material has given rise to much speculative thought, and will be referred to later on in this paper.

We have what is known as a set of accessory thyroids, and having a similar structure to that of the thyroid, no doubt their functions are somewhat similar.

The parathyroids are quite different in structure, being composed of solid masses of epithelial cells which are not arranged in vesicles, and contain no colloid material. It has been demonstrated that when the parathyroids alone are removed the animal dies quickly with acute symptoms, muscular convulsions, tetany, etc.; while if the thyroids alone are removed the animal may survive for a long period, but develops a condition of malnutrition, a slowly increasing cachexia, which may later assume a condition resembling myxedema in man.

We find after a cursory study of these glands, that after any form of traumatism or disease which may cause hypofunction or stagnation of their secretion, quite an array of peculiar symptoms arise. The mental forces become weakened and inactive, the skin becomes thick and immobile, owing to a collection of mucine-like material in the corium, the connective tissue fibrils thicken, and the hair falls out. Weakness of the muscles and disturbance of sensation are associated with a general loss of intelligence.

While these and many other pathological symptoms and conditions are the result of any serious impairment of the thyroids causing a loss of function, we have on the other hand from hyperfunction of the thyroid such a condition as exophthalmic goiter (Graves' disease), with all of the horrible

*Read before the State Medical Society of Virginia, Nov. 2, 1917.

symptoms and suffering that usually accompany that disease, such as tachycardia, syncope, asphyxia, and asthmatic breathing from excessive pressure, etc.

In discussing the subject of internal secretions we do not confine our argument simply to the ductless glands, but include the pancreas, ovaries, and other internal secreting glands.

The thymus gland, about which there has been much speculation of late years, belongs to the ductless class, and its physiological function is yet quite obscure. Formerly this gland was supposed to reach its full development at birth, and subsequently to atrophy, being replaced by a growth of lymphoid tissue, but of late this belief has been abandoned and many observers have learned that it continues to grow, and that true thymus tissue may persist through life. Its proximity to the thyroids and parathyroids, and its similarity in origin would indicate that, like them, it may have some important specific influence upon metabolism.

There seems to be some reciprocal relation between this gland and the reproductive glands. We find that when this gland is removed it hastens the development of the testes, and when the testes are removed the thymus becomes slightly enlarged for a time prior to a retarded atrophy (Henderson). There is no doubt in my mind that a similar relation holds good in females under like conditions. And if we will read between the lines and take the time to consider, we may be able to account for much of the peculiar phenomena that follow the spaying of our women by "unbaked" gynecologists.

It is a well known fact among writers on the subject of internal secretions that the ovaries play an important part in the nutrition of both body and mind. In gynecological practice it is often observed that following complete removal of the ovaries with the premature menopause that ensues, we find many distressing symptoms, both mental and physical. There are cases whose mental condition becomes so serious that they are fit subjects for an insane asylum.

It was the writer's unfortunate privilege some years ago to attend a number of this class of mutilated patients who had undergone complete ovariitomy. All honor to our modern gynecologists for their conservatism in the matter of not removing *in toto* these important glands from our young and middle-aged females.

One of the class of these patients above referred to, attended by the writer was a refined, highly cultured lady of twenty-six, who had been for some time previous quite nervous, bordering on hysteria. Acting on the advice of her relatives, she went to her young uncle's sanatorium in a distant city for treatment, and was operated upon for *supposed* cystic ovaries and hysteroepilepsy. Within a few months following the operation she began to run down both physically and mentally. At regular monthly intervals she had attacks of hallucination or cyclic insanity preceded by a state of moroseness. At other times her mind would appear almost normal, but this lasted only a short while, when she would gradually revert to the abnormal. This patient was under my observation at intervals for several months. She seemed to find temporay relief in coming to my office at irregular intervals to take electricity and vibratory massage administered by a trained nurse under my careful supervision. If I had been accessible to some reliable manufacturer of ovarian extract I should have administered a thorough course of it, aided by other constructive treatment.

To keep this young lady out of the lunatic asylum and save her family from the remorse, I sent her to a specialist's sanatorium for the treatment of nervous diseases where she remained only a few weeks prior to being sent back home to die. Being absent from the city when she returned, I failed to see her, but was informed that her physician diagnosed her last illness as cerebrospinal meningitis. This, in my judgment, was the closing scene of a typical case of abnormal internal secretions, complicated by autointoxication, superinduced by the complete extirpation of both ovaries of this young woman.

In older literature it was affirmed that not only the entire nature of woman, but her character as well, depended on the reproductive organs. Heimont said: "Propter solum uterum mulier est, quod est." Chereau said: "Propter ovarium solum mulier est, quod est."

Virchow's statement that a woman is a woman simply because of her generative glands, is familiar to us all. Prof. Hochwart, in the *American Journal of the Medical Sciences*, deliberately states that, "The peculiarities of woman, both in body and mind, in fact, all the femininity which we admire in the true woman, are dependent on the ovary."

Every up-to-date physician and neurologist who has had ten years experience is quite familiar with these cases of psychoneurosis among our women of the past decade, who had been operated upon.

The function and sacred mission of these important organs are being studied with more care and zeal during the past half decade, and instead of the radical a more humane operation is being advised by our leading gynecologists, giving more consideration for after results.

These psychoses are well known to the careful observer, from early puberty to the menopause, in a very large percentage of women who may be apparently healthy in all other respects. Recent investigations have shown that the menstrual life of women is not a suddenly appearing or disappearing event. On the contrary, the phenomena seems to be a continuous wave-like condition which is not found before the beginning nor after the close of menstruation, either in early youth or old age. Much of the variability of mood and disposition may be explained in this, the often inexplicable vacillating temperament, in the sexually mature woman.

The question of the not infrequent insanity during menstruation has been likewise discussed. Suicides have been frequent at these times. A. Pilez found intramenstrual changes of the sexual organs in more than one-third of female suicides.

Among fifty-six shoplifters, Legrand Soulle found that thirty-five were "unwell" at the time of the crime. Icord who has written quite extensively on the subject of internal secretions observes that in perusing the diary of a young girl it does not require much perspicacity to discover the pages which were written during menstruation.

We observe these psychic disturbances at the climacterium, which is considered the most dangerous and critical age of woman. At the time when menstruation begins to be irregular, sometimes even months or a year before, women fall into a strange state of unrest, sometimes accompanied by sexual over-excitability. Deep depression, a tendency to outbreaks of weeping, periods of irritability, psychic vacillations, a decrease of intelligence, evil forebodings, etc. These are some of the well known conditions in a large percentage of women during this critical time. In some cases it reaches a very high degree of psychosis, as is shown in the following case that came under the writer's observation.

A lady of 46 years, whose family history was negative so far as I could ascertain. Her peculiarities in temperament and disposition were such that her family life was anything but pleasant; her husband, who was a railroad man, was living apart from her, her two married sons could not tolerate living under the same roof with her, hence we can only surmise the kind of life she was living. After the first day or so of her entrance into my private sanatorium I made several very thorough examinations and found quite an array of abnormal conditions, both physical and mental. Among the physical my attention was first drawn to her enlarged thyroids and slightly protruded eyeballs (exophthalmos), fast and nervous heart sounds, marked tenderness over both ovaries with slight protuberance and tympanites; speculum examination showed a double laceration of the cervix, an endometritis with catarrhal discharge, clitoris double the normal size; urinary analysis revealed albumin and casts with s.g. 1.010 (24-hour specimen). The mental symptoms at this and subsequent examinations were: Hysteria, melancholia, insomnia, psychic blindness, syncope, nymphomania, etc. My diagnosis and treatment at the time (several years ago) were both purely symptomatic, but to-day I would diagnose this case as one of simple "abnormal internal secretions complicated with nephritis and lacerated cervix." The first week's treatment consisted of absolute quiet in bed under special trained nurse and nervines with special diet; second week operation for lacerated cervix and curettage of the uterus under local and H. M. C. anesthesia; during the third, fourth and fifth weeks I administered the dry-hot-air treatment (Sprague method) with massage, and a strict select cereal and milk diet. At the end of the seventh week the patient was dismissed as partially cured. My last account of this patient was that she was doing light housekeeping and other ordinary household duties, and had had a reconciliation with her husband and former friends.

This is only one of many similar cases that the general practitioner meets and puzzles his brain over, and then wonders why we know so little when there is so much yet to learn.

Would that our physiologists and anatomists, our chemists and laboratory workers would delve a little deeper into their respective sciences and bring to surface the respective functions and anatomical relation of these ductless and other internal-secreting glands, with their special bearing on metabolism and mental forces.

We have the pancreas and its allied coworker, the liver, with their peculiar generating and secreting forces producing pathological conditions such as diabetes mellitus, a disease about which, until within the past decade or so, we knew but little. And even at this late day we are guessing between abnormal internal secretions and faulty metabolism with their respective relation to the islands of Langerhans as the real factor in the etiology of this well known disease. The fell symptom of acidosis in the production of diabetic coma in this disease points very conclusively to the fact that faulty metabolism plays an important rôle in diabetes.

We have conditions very similar to these in certain diseases of the kidney when the functions of that organ become impaired to such an extent as to cause uremia with its long train of mental and physical symptoms. When we consider the vast array of psychic symptoms and phenomena produced by faulty metabolism and deranged internal secretions we become somewhat bewildered in differentiating these conditions from some of the ordinary forms of insanity. No doubt many a poor devil has been sent to a lunatic asylum on account of some sudden outbreak of anger or other erratic act due to dysfunction of some one or more of the ductless glands or possibly to deranged body metabolism.

Since we have discovered that there is direct communication between the sympathetic nervous system and the ductless glands, we can the more readily understand why these organs with their secretions become influenced by mental emotion either of anger or distress. Many cases of melancholy, hypochondriasis, etc., may be caused by derangement of the internal secretions. We may also have mental perversions, a lack of control of the sexual passions and anger. Our paranoiacs with their cunning schemes, our alcoholic and drug fiends, our eccentric, so-called religious fanatics who are suddenly and without preparedness called by a Higher Power to preach some strange emotional doctrine, dogma, or cult. These are only a few of the pathological effects of abnormal internal secretions on mental depravity. We have the various kinds of faulty metabolism that give rise to the purine bodies such as uric acid, xanthine, guanine, etc. We also have the toxins that are set free, and invade the entire system when these ductless and other internal secreting glands become impaired, causing every imaginable form of mental perversion such as illusions, hallucinations, etc. The cardinal feature of the pathogenesis of various forms of insanity is involved in this connection, since the foregoing data and illustrations clearly indicate that hypothymia and hypothyroidism may, by inhibiting the efficiency of the defensive functions of the ductless glands in general, entail a pathological toxemia capable of evoking mental disorders. Hypofunction of any of the ductless glands may give rise to toxemia by simply depriving the system of this regulating or harmonizing fluid whose function is to destroy the toxins. This is especially true of the parathyroids, since we know that tetany is nothing other than a form of toxemia caused by hypofunction of these glands.

Then as a result of the deficiency of the nucleins, the catabolic phase of metabolism is also impaired, and toxic wastes accumulating in the blood, including that which circulates in the brain cells, catatonic phenomena are invited. Chemical changes in the cortical cells of a degenerative type may ensue, causing autointoxication. After a study of the fundus of the eye in 109 consecutive cases of this character, H. L. Tyson and L. Pierce Clark deliberately state that the visual syndrome, as observed by them was, "a distinct contribution to the theory that dementia precox is an autotoxic disease, and that the poison is primarily vascular, which finally induces neuronic degeneration.

Concerning the genesis of the poison, these au-

thors, with many others, conclude that the syndrome points conclusively to the fact that this toxin is generated in the gastrointestinal tract.

To antagonize the intoxication by any wrong method of treatment, the ductless glands which take part in the defensive functions of the body, the thyroids, the parathyroids, and the adrenals become abnormally active in some instances, and incidentally excite the dystrophic brain cells, provoking the catatonic form of the disease (Sajous).

Dercum and Ellis, in a postmortem study of eight patients suffering from dementia precox, all of whom had succumbed to tuberculosis, found that in seven the thyroid was under weight. The other seven glands showed colloid abnormalities, both quantitative and qualitative, and four showed retrograde changes in the acinal epithelial cells. The adrenals, on the other hand, showed a marked excess in weight.

It is a well-known fact that 65 per cent. of all idiots, before the age of six years, are deprived of the thymus gland (Sajous). It is also a fact that this class is more susceptible to infectious diseases, and about the same percentage succumb to these infections. Many die of tuberculosis in the incipient stage. As previously intimated, when we have a suppression or stagnation of the secretions of any one or all of the ductless glands, we may have a state of degeneracy of both mind and body. We may have amentia, ranging from the slight backwardness of the moron or imbecile to profound idiocy, including the amaurotic, moral, and microcephalic forms. Hebephrenic phenomena of melancholic type incident upon puberty are quite noticeable among school girls who rarely pass the intermediate grade of the public high school.

It is not within the scope of this paper to discuss fully the hyperfunction of the glands of internal secretion. When, however, in the presence of toxemia, we have clear evidence of overactivity of these organs, it is reasonable to conclude that we are dealing with a defensive reaction. If, after a trial of the desiccated thyroids and iodothyrin, we observe an increase of the motor symptoms of catatonia and those peculiar to Graves' disease, such as rapid pulse, muscular tremors, hyperhydrosis, overactive eye reflexes, increased muscular excitability, dermographia, loss of weight, and skin pigmentation, we may reasonably conclude our diagnosis. The only clear indication, in our judgment, is a partial thyroidectomy, which has proven quite successful of late. Dr. Fallis treated by this method eight successive patients with "catatonia," who recovered their mental integrity. This treatment applies more particularly to the young than to the old and long standing cases. In mild cases of dementia precox, we might administer a thorough course of thymus extract aided by lecithin, which is a phosphorus compound, and is indicated in the treatment of the active nervous symptoms of both catatonia and Graves' disease. Dr. Bayard Holmes adds emphasis to the importance of this subject when he writes: "There is no disease, not even general paresis, that finds the profession in so helpless, hopeless, and pitiable a condition as dementia precox does." There is no disease that costs the state a larger amount in care and custody than this disease. According to various estimates it represents about 25 per cent. of the total admissions to the institutions of the insane (Ingham).

In view of these established facts, sanctioned by such men as Sajous, Dercum, Hochwart, Howell, and L. F. Barker, from whose able pens I have learned much and quoted liberally in the preparation of this paper, let us as progressive medical men and humanitarians, give the subject of internal secretions more zealous study, and use our influence toward the establishment of institutions for the study and treatment of psychiatry and its relation to internal secretions and metabolism. By this lofty endeavor we may relieve the profession of the stigma of permitting 30 per cent. of our fellow mortals to be doomed to the asylum for the insane.

"More might be said hereof to make a proof,
Yet more to say were more than is enough."

DEATH AND ITS SEMITIC TRADITIONS.

By JOSEPH H. MARCUS, M.D.,
ATLANTIC CITY, N. J.
ATTENDING PHYSICIAN TO THE JEWISH SEASIDE HOME.

IN the Bible death is viewed under form of an angel sent from God, a being deprived of all voluntary power. Throughout the Bible are mentioned the following: The "angel of the Lord" smites 185,000 men in the Assyrian camp; "the destroyer" kills the firstborn of the Egyptians, and the destroying angel rages among the people of Jerusalem. In I Chronicles xxi:15 the "angel of the Lord" is seen by David standing "between the earth and the heaven, having a drawn sword in his hand stretched out over Jerusalem." Job uses the general term "destroyer," which tradition has identified with "destroying angels," and Proverbs xvi:14 uses the term the "angels of death." The rabbis found the angel of death mentioned in Psalms lxxxix:45, where the translation reads: "There is no man who lives and, seeing the angel of death, can deliver his soul from his hand." Ecclesiastes viii:4 is thus explained in the passage: "One may not escape the angel of death, nor say to him, 'Wait until I put my affairs in order,' or 'There is my son, my slave; take him in my stead.'"

The angel of death occurs very frequently in rabbinical literature. Where the angel of death appears there is no remedy. If one who has sinned has confessed his fault, the angel of death may not touch him. By acts of benevolence, the anger of the angel of death is overcome; when one fails to perform such acts, an angel of death will make his appearance. God commands the angel of death. As soon as he has received commission to destroy, he does not discriminate between the good and the bad. In the city of Luz, the angel of death has no power, and when the old people are prepared for death they leave the immediate precincts of the city, and die in the outskirts. A legend to the same effect existed in Ireland in the Middle Ages.

The angel of death was created by God on the first day. His dwelling place is in heaven, whence he reaches the earth in eight flights, whereas pestilence reaches it in one day. He has twelve wings. "Over all people have I surrendered to thee the

power," said God to the angel of death, "only not over this one which has received freedom from death through the law." It is said of the angel of death that he is full of eyes. In the hour of death he stands at the head of the departing one with a drawn sword, to which clings a drop of gall. As soon as the dying individual sees the angel he is seized with a convulsion, opens his mouth, whereupon the angel of death hurls the drop into it. This drop is the cause of his death, and he turns putrid and his face becomes yellow. The expression "the taste of death" originated in the conception that death was caused by a drop of gall. The soul is said to escape through the mouth or, as is mentioned elsewhere, through the throat; therefore the angel of death stands at the head of the patient. When the soul forsakes the body its voice travels from one end of the world to the other, but it is not heard. The drawn sword of the angel of death indicates that the angel of death was regarded as a warrior who kills off the children of men. "Man, on the day of his demise, falls down before the angel of death, like the beast before the slayer."

In later representations the knife sometimes is substituted for the sword, and reference is also made to the cord of the angel, which indicates death by throttling. Moses said to God, "I fear the cord of the angel of death." Of the four methods of execution in this period, three are named in connection with the angel of death: burning (by pouring hot lead—the drop of gall), slaughtering (by beheading), and throttling. The angel administers the particular punishment which God has specified for the commission of sin. A peculiar mantle belongs to the equipment of the destroyer. The angel of death assumes the particular form which will best serve his purpose; *e.g.* he appears to a scholar in the form of a beggar imploring pity. "When pestilence rages in the town, walk not in the middle of the street, because the angel of death (pestilence) strides there; if peace reigns in the town, walk not on the edges of the road. When pestilence rages in the town go not alone to the synagogue, because there the angel of death stores his implements. If the dogs howl, the angel of death has entered the city; if they make sport, the prophet Elijah has come." The "destroyer" (Satan Hamashhit) in a daily prayer is represented as the angel of death.

There are six angels of death: Gabriel over kings; Kapziel over youths; Mashbir over animals; Mashhit over children; Af and Hemah over man and beast.

When the Messiah comes all the dead will arise, and there will be an end to death, for the angel of death will be himself destroyed by the Messiah. The last enemy that shall be annihilated is death: the same idea seems to be expressed in the book of Jubilee, 29 and xxiii: "And they shall fulfill all their days in peace and joy and shall live on, since there will be no Satan and no evil to destroy them." The angel of death, who is identified with Satan, immediately after his creation had a dispute with God as to the light of the Messiah. When Eve touched the tree of knowledge she perceived the angel of death and thought: "Now I shall die, and God will create another wife for Adam." Adam also had a conversation with the angel of death.

It was Moses who most often had dealings with the angel. At the rebellion of Korah, Moses saw him. It was the angel of death in the form of pestilence which snatched away 15,000 every year during the wandering in the wilderness. When the angel came to Moses and said, "Give me thy soul," Moses called to him, "Where I sit thou hast no right to stand," and the angel retired in shame and reported the incident to God. Again God ordered him to bring the soul of Moses. The angel went and, not finding him, inquired of the sea, the mountains, and of the valleys; but they knew nothing of him. Really Moses did not die through the angel of death, but through God's kiss (bineshkah); *i.e.* God threw his soul out of his body. Legend seizes upon the story of Moses' struggle with the angel of death, and expands it at length.

Solomon once noticed that the angel of death was grieved. When questioned as to the cause of his sorrow he answered: "I am requested to depart with your two beautiful scribes." Solomon at once charged the demons to convey his scribes to Luz, where the angel of death could not gain access. When they were near to the city, however, both perished. The angel laughed on the next day, whereupon Solomon inquired as to the cause of his mirth. "Because," answered the angel, "thou dist send the youths thither, whence I was commanded to bring them." In the next world God will permit the angel of death to fight with Pharaoh, Sisera, and Sennacherib.

The teaching of God shields one from the power of the angel of death. The children of Israel have accepted the Torah (the five books of Moses—Genesis, Exodus, Leviticus, Numbers, and Deuteronomy) only that the angel may exert no power over them. Since death can only result from sin, it cannot, of course, come to those who live in accord with the Torah. Although the sentence of death once pronounced could never be recalled, yet the angel may not visit teachers of the law; he is, on the contrary, their friend, and even imparts knowledge to them.

Teachers of the law of the fourth century associate rather familiarly with him. When he appeared to one on the street, the instructor reproached him with rushing upon him as upon a beast; whereupon the angel called upon him at his house. To another he granted a respite of thirty days, that he might put his affairs in order before entering the next world. To a third he had no entry, because he was powerless to interrupt the study of the Talmud. To a fourth he displayed a rod of fire, whereby he is recognized as the angel of death. Oftentimes does he resort to cunning means to approach and seize his victims.

The death of Joshua ben Levi, in particular, is enhanced with a web of fable. When the time came for him to die and the proverbial angel of death appeared to him, he demanded to be shown his place in paradise. When the angel had consented to this, he demanded his knife that the angel may not frighten him on the way. This request was also granted him; and Joshua sprang with the knife over the wall of paradise; the angel, who is not allowed to enter paradise, caught hold of the end of his raiment. Joshua swore that he would

not come out, and God declared that he should not leave paradise unless he was absolved from his oath; if not absolved, he was to remain. The angel of death then demanded back his knife, but Joshua refused. At this point a heavenly voice rang out: "Give him back the knife because the children of men have need of it."

In Arabic Literature, the angel of death is spoken of in the Koran, and is called by the Mohammedans, Azrael. "When death was created by God, he, on account of his terrible power, had to be put in seventy thousand chains of a thousand years' journey's length each, and behind millions of barriers. When Azrael was placed in charge of him, and saw him he called the angels to look at him; and when he, at God's command, spread his wings over him and opened all his eyes, the angels fainted away, and remained unconscious for a thousand years. Azrael was given all the powers of the heavens to enable him to master death."

Azrael reaches from one end of the world to the other and has seventy thousand feet and four thousand wings. His entire body is covered with eyes and with tongues as numerous as the living creatures on earth. When any of these latter die a corresponding eye bulges forth. At the end of the world all these eyes, excepting eight, are plucked out by God; those of Israfil, Michael, Gabriel, Azrael, and the four "Hayyot" of the heavenly chariot alone remaining. The times of the death of persons is made known to the angel of death through the roll-book in his possession, showing the white stripe around the name of the person doomed. Forty days before death, however, a leaf falls from the tree of life, under the throne of God, into the lap of Azrael, who is seated in the seventh heaven, thus announcing the death.

"When people lament and weep too much over the departed person the angel of death shall stand at the door, and say: 'What cause have you for such violent complaint? I am only the messenger of God and have done His bidding, and if you rebel against Him I shall return often and take one of your house.' When a righteous person dies, the angel comes with a host of good angels carrying sweet odors of paradise and makes the soul leave the body like a drop taken out of a bucket of water. When a wicked person dies the angel of death comes in the company of demons, who pull the soul out as with iron spits."

The ancient Hebrews expected to be gathered to, or sleep with, their fathers when death befell them, and feared only the idea of going down to Sheol (pit or destruction) mourning. To sleep and be at rest was the desire of the distressed. To die in "a good old age" was regarded as a blessing; to be cut off from the land of the living in the noontide of life was dreaded and looked upon as a calamity. Only at times the stings of mortality and the stroke of Sheol became objects of horror, from which the Lord was petitioned to redeem men. Nowhere, however, in the Bible is death regarded as a genuine evil, except from the point of view that man, being of divine origin, should have had, like any other heavenly being, access to the tree of life, and have existed forever. Accordingly, the eschatological view found expression in such phrases as that "death shall be swallowed up forever" and "the dead shall rise again." Satan is called in the New Testament "a murderer from the beginning" and the "destroyer." Death is conceived of as a person who has charge of the shades in the nether world. He is their general. The following is a description of death as one of God's messengers:

"When Abraham had refused to let the archangel Michael take his soul, God said to the latter: 'Call Me hither, death of the shameless countenance and pitiless look.' Death shivered and trembled at being called to come before the Lord, when God said to him: 'Come hither, thou bitter and fierce name of the world, hide thy fierceness, cover thy corruption, and cast away thy bitterness from thee, and put on thy beauty and all thy glory and go down to Abraham, My friend, and bring him to Me.' Death put on a robe of great brightness, and made his appearance like the sun, and became fair and beautiful above the sons of men, assuming the form of an archangel, his cheeks flaming with fire, and went to Abraham, a sweet odor and a flash of light, announcing his coming to the patriarch, who took him to be an archangel, the chief captain of God, and welcomed him as the purveyor of light and the most glorious helper. But death rejoined: 'Most righteous Abraham, I am the bitter drop of death,' and when asked for his errand he said: 'For thy holy soul have I come.' Abraham again refused to relinquish his soul. Death followed him into his chamber, and when Abraham laid down upon his couch he sat by his feet, and would not depart, notwithstanding all the entreaties of the patriarch to let him live.

"On inquiry of the patriarch, he told him that only because of his great righteousness, his hospitality to man, and his love toward God, which became a crown of glory upon his head, did he approach him in such beauty and glory; to sinners he came in fierceness, and corruption, and bitterness. 'Show me these,' asked Abraham, but death replied, 'Thou canst not stand these looks.' Thereto Abraham answered: 'By means of the name of the living God, I shall be able to look.' So death put off his sunlike glory and put on his tyrant-like robe and made his appearance fiercer than all wild beasts, and filthier than all filth, and he showed Abraham seven fiery serpents' heads and fourteen faces: (1) of flaming fire, (2) of darkness, (3) of a viper, (4) of a precipice, (5) of a fierce asp, (6) of a terrible lion, (7) of a cerastes, (8) of a basilisk, (9) of a fiery scimitar, (10) of terrible lightning and thunder, (11) of a stormy sea, (12) of a rushing river, (13) of a three-headed serpent, and (14) of a cup filled with poison; and then he showed him every mortal disease emanating from the odor of death. Seven thousand man-servants and maid-servants of Abraham died from the effect of this odor and sight, so that Abraham implored death to hide his fierceness and to put on his former garb of beauty. Death complied with his request, and joined Abraham in a prayer to God to restore to life those who had died so suddenly by his fierceness, and the prayer was granted.

"Abraham, however, would not consent to surrender his soul until death had explained to him the different forms and faces he had displayed to

him in all their fierceness; whereupon death answered that the seven heads of the serpents indicated the seven ages during which he is to destroy all men, rich and poor, and to bring them to the bottom of Hades. Because people die by fire, by falling from precipices, by the sword, by rushing rivers, on the raging sea, and in storms of lightning, by wild beasts, or cups of poison, he assumed all those aspects. Finally, he spoke of the seventy-two kinds of death, and of the death of the holy. Then death took the right hand of Abraham, and his soul clung to him."

Death appears here as the personification of psychic evil, with numerous traits, but not of moral evil.

There are different views among Jews concerning death, and its cause. Some assign it to Adam's first sin in partaking of the forbidden fruit. This point of view is somewhat modified by the rabbis, who regard death as the fruit of personal sin, maintaining that, like Adam, each person dies on account of his own sin, as "there is not a righteous man that doeth good sinneth not" (Ecclesiastes vii:20). Still the rabbis speak of a number of "saintly men who died without sin and only in consequence of the poison of the serpent": *e.g.* Benjamin, Amram, Jesse, the father of David, and Chileab, the son of David. Another view is that death was ordained at creation, and that Adam by his sin merely hastened death. According to others, Adam was destined to live forever and not to taste death, but, owing to the fact that men like Hiram of Tyre and Nebuchadnezzar wanted to be worshiped as Gods, God decreed death for man. The opinion is also expressed that God would have annihilated the power of the angel of death over Israel after its acceptance of the law, but for the fact that the decree could not be altered. From the point of view that sin precedes and causes death in each person, the Talmud designates special reasons for the death of innocent children.

Modes of Death.—There are 903 distinct deaths. The hardest is by asthma, and the easiest is called "death by the kiss" which is "like drawing hair out of milk," that is the interpretation of "by the mouth of the Lord." Six persons are known to have died in this manner; namely, the three patriarchs, and Moses, Aaron, and Miriam.

Death coming after an illness of five days' duration is considered an ordinary occurrence; after four days a reprimand from heaven; after three days a severe rebuke; after one day, a sudden one, or, according to some, an apoplectic one. To die before reaching the age of fifty is designated as "being cut off." Sixty years is a ripe age; seventy is old age, and eighty is advanced age.

Many allegorical tales are related in rabbinical literature regarding the communication of the dead with the living. A pious man, being censured by his wife for giving away a dinar (a Roman silver coin worth about fourteen cents) to a mendicant in time of famine, went to sleep in the cemetery. It was New Year's eve, and he overheard the spirits of two women gossiping. One of them proposed to fly and listen behind the curtain in the judgment chamber to the promulgation of the future visitations in the world. The other spirit excused herself, saying: "I cannot accompany thee because I am buried in reed matting; go thyself and come back and tell me what thou hearest." Presently her companion returned and reported: "I heard that the hail will kill whatever is planted in the first rainy season." The pious man planted in the second rainy season. The following year he again went to sleep in the cemetery on New Year's eve, and overheard a similar conversation, gaining the information that whatever was planted in the second season would be consumed by blight. The pious man planted during the first season. His wife was curious to know how he managed to evade the calamitous visitations, and he, being pressed, related his story. A few days later the woman had a quarrel with the mother of the second spirit, and abused her for giving her daughter an indecent burial. The third year the pious husband again sought to obtain information regarding future crops. The second spirit said: "Hush, companion! Our former conversation was overheard by mortal man."

The dead are supposed to take an active interest in worldly affairs. The assertion of one authority that "the dead know not anything" is interpreted, "the wicked who are considered dead while yet alive." R. Isaac said, "The sting of a worm to the dead is like the pricking of a pin to the flesh of the living." The dead are very sensitive. One must not tell tales around the deathbed of a scholar. Inasmuch, however, as the dead are exempt from performing the precepts, they feel slighted if such performance should take place in their presence by the living, as it would be like "mocking the poor." In burying a scholar it was customary to deposit in his coffin a scroll that was unfit for reading.

The practice of praying for the intercession of the dead is of early origin. Caleb on entering Hebron visited the cave of Machpelah and prayed to the patriarch to be saved from cooperating in the conspiracy of the scouts sent by Moses to make a report of the conditions existing in the Holy Land. The Talmud mentions the custom of visiting the cemetery to request the dead to pray for the living. The noise of the soul's departure from the body reverberates through the world from one end to the other, yet the sound is unheard. Prior to the exit of the soul it sees the Shekinah (the majestic presence or manifestation of God which has descended to "dwell" among man). The soul after death is in the same condition as it is in life when one dreams. Until the body is entirely consumed the soul hovers over the grave. Samuel said: "If one wants to have a taste of death, let him sleep with his shoes on." "And God saw everything that He made, and behold it was very good." This includes death. "The day of death (is better) than the day of one's birth" is explained to mean that death tells of the meritorious life of the departed; it is like the vessel entering port laden with goods. The great ones of each generation must die to make room for the greatness of successors; "the righteous themselves ask for death as a favor." The Zohar (a commentary on the Pentateuch) calls death a festal day, and the day upon which Adam died was made a holiday.

The windows of the death chamber should be opened to allow the spirits to enter and to depart.

The angel of death is supposed to wipe his bloody knife in water near the dead; hence all water of the adjacent houses must be emptied on the ground. As the "shedim" (demons) are supposed to follow the dead or to wander around their graves, those who follow a funeral cortege must wash their hands on their return, before entering a house; but should not dip them in a river. A special lavatory for this purpose is usually provided at the cemetery. On returning from the funeral one should sit down and rest on the way several times, so as to drive away the spirits that follow them. The board upon which the dead is cleansed must not be turned over. One should not visit the same grave twice during one day, nor sleep in a cemetery, nor look closely upon the face of a deceased person, nor kiss the dead, not even when a near relative.

A common superstition is current that if the shadow of one's head is invisible against the wall in a house where a light is burning on Hosha'na Rabbah (the popular name for the seventh day for the feast of Booths) eve, it is a sign that the person will perish within the year. If visible, he will live. R. Ammi says, "If one wishes to ascertain whether he will live during the following year, let him, during the ten penitential days, burn a candle in his house where no wind can extinguish it. If it is not blown out he will live; otherwise not." To discover whether the husband or the wife will die first, calculate the numerical value of the letters in the names of both. If the amount is even the man will expire first; if odd, the woman.

Fanaticisms relative to death in connection with dreams are quite numerous. One of them, the vision of a scroll in the ark, presages death, as the demise of Aaron follows the description of the tablets placed in the ark. A dying child may be released from the grip of dissolution, if nominally sold by the parents to a friend for a shekel. A change of name may save one from mortality. The removal of a feather pillow from beneath the bed of a dying individual aids the soul in an easier departure. Some rabbis objected to this custom, on the supposition that it disturbed the patient and so hastened his demise. The iron keys of the synagogue, if placed under the pillows, are believed to accomplish the same effects. Announcement of a death should be made in an indirect manner, and it was for this reason that the shofar (the ancient ritual horn of Israel) was blown in talmudical times when death occurred in a town. The beadle who summons the congregation to early morning prayer and devotion, by knocking three times on their doors or windows, announces a death by reducing the number of raps to two. It is a happy omen to die with a smile on the face, or to die on one's birthday. Rain on the day of one's funeral is a sign of pity and condonation toward the departed. It is habitual to bend the thumb of the corpse so that the entire hand resembles the word "Shaddai" (Almighty), and to bind it in this position with certain fringes. A shard is placed over the eyes, a little stick in the hands, a piece of metal on the body, a small bag of earth from the Holy Land under the head, and a three-toothed wooden fork in the hand, to enable the dead to excavate a subterranean passage to the Holy Land on the day of resurrection, when all the Jewish dead will arise in Palestine. A towel is hung up and a glass of water placed next to it, so that the soul might bathe when it returns to the body.

To demons were ascribed the various diseases, particularly such as affect the brain and the inner parts. In the main they were perpetrators of great harm to the body. There were a great many supposed to exist, some of which are mentioned below. "Shabriri" (lit. dazzling glare), the demon of blindness, who rests on uncovered water at night and strikes those with blindness who drink of it; "Ruah Zeradah," the spirit of catalepsy; "Ruah Zelatah," the spirit of headache, hovering on palm trees; "Ben Nefilim," the demon epilepsy; "Ruah Kezarit," the spirit of nightmare; "Ruah Tezazit," the spirit of delirious fever and madness; "Ruah Zara'at," the spirit of leprosy; "Ruah Kardeyakos," the spirit of melancholy; "Shibetta," a female demon, bringing croup to persons, especially to children, who do not wash their hands in the morn; "Bat Horin," a demon bringing a disease of the eye to one who fails to wash his hands after meals; "Kuda," a demon who attacks women in childbirth; "Eshshata," the demon of fever; "Ruah Zenunim," the spirit of sexual desire; "She'iyyah," an ox-like fiend dwelling in desolate homes; "Puta" or "Pura," the spirit of forgetfulness; "Ben Temalyon," the demon of St. Vitus' dance.

These demons were supposed to enter the body and cause the disease, while overpowering or "seizing" the victim; hence the ordinary cognomen for "epileptic" is "nikpeh." The synonymous Greek word means the state of being in the authority of exorcism. To cure such diseases it was necessary to draw out the evil demons by certain incantations and talismanic performances. Josephus, who speaks of friends as "spectres of the wicked which enter into men that are alive and kill them," but which can be driven out by a certain root, witnessed such a performance in the presence of the Emperor Vespasian, and attributed its inception to King Solomon.

In the Book of Wisdom, Solomon claims to have received from God power over the demons. The same potency of curing by demonism such diseases as dumbness, blindness, epilepsy, mania, and fever were exercised by Jesus and His disciples, as also by their Jewish contemporaries. Occasionally a demon is called "Satan": "Stand not in the way of an ox when coming from the pasture, for Satan dances between his horns." The name "mashhit" (destroyer) seems to refer to the head of the demons in the sentence: "When permission is given to the destroyer to do harm, he no longer discriminates between the righteous and the wicked." The queen of demons is Lilith, pictured with wings, and long flowing hair, and called the "mother of Ahriman." "When Adam, doing penance for his sin, separated from Eve for 130 years, he, by impure desire, caused the earth to be filled with demons and evil spirits." And it was Lilith, as Adam's concubine, who bore them.

Birds as Souls.—In Psalm xi:1 the soul is compared to a bird: "Flee as a bird to the mountain." As living beings that move and fly through the air birds have suggested themselves at all times and in all lands to primitive man as images of the soul, the name for which in most languages is taken

from breathing ("nefesh," "neshamah" = "anima" or "psyche"); the soul was represented in the form of a butterfly, as illustrated by the tombs of the early Christians. The soul of the king of Egypt was pictured on the monuments as a bird, and the genius of the kings of Persia and Assyria retained the wings of the bird. The Arabs also regarded the soul as a bird, and believed that after death it hovered at times around the body, screeching like an owl. This view was shared by the Jews. They placed credence in the supposition that all souls are gathered in a great cage or treasure house in heaven, a columbarian, called "Guf"; and so Rabbi Asi taught that the Messiah, the son of David, cannot come until all the souls have been taken out of the Guf, and have gone through human bodies. In the Greek Baruch Apocalypse, Baruch sees in the fourth heaven a lake full of birds, and is told that these are the souls of the righteous, who continually sing the praise of God. These stories are repeated by Christian saints who affirm having seen the souls of the devout in paradise. In the zohar the sparrow and the swallow, spoken of in Psalm lxxxiv:3, are compared to the souls of the religious which dwell in paradise. Three times a year, they rise upon the walls of paradise and sing the praise of the Master of the universe, whereupon they are ushered into the palace where the Messiah is secreted, called the great "Souls' Nest." They are adorned with crowns in his honor when he appears to them, and from beneath the altar of heaven, where dwell the souls of the pious, they prepare the erection of the temple of the future. It is customary among certain Jews, when a death occurs, to open a window in order that the soul may fly away like a bird.

As previously recounted, the dead are assigned to a place called "Sheol," which connotes a locality where those that had passed away were believed to be congregated. Jacob, refusing to be comforted at the supposed death of Joseph, exclaims: "I shall go down to my son a mourner unto Sheol." (Genesis xxxvii:36) Sheol is underneath the earth and is very deep and it marks the point at the greatest possible distance from heaven. The dead descend or are made to go down into it; the revived ascend or are brought and lifted up from it. Sometimes the living are hurled into Sheol before they would naturally have been claimed by it, in which cases the earth is described as "opening her mouth." Sheol is spoken of as a land, but ordinarily it is a place with gates, and seems to have been viewed as divided into compartments with "farthest corners" one beneath the other. Here the dead meet without distinction of rank or condition—the affluent and the indigent, the pious and the iniquitous, the master and the bond servant—if the portrayal in Job iii refers, as most probably it does, to Sheol. The dead continue after a fashion, their mundane existence. Jacob would mourn there (Genesis xxxvii:35, xlii:38); David abides there in peace (I Kings ii:6); the warriors have their weapons there with them (Ezekiel xxxii:27), yet they are mere shadows.

The following extracts, also, are quoted in the Bible: The dead merely exist without knowledge or feeling. Silence reigneth supreme, and oblivion is the lot of them that enter therein. Hence it is known also as "Dumah," the abode of silence, and there God is not praised. Still on certain extraordinary occasions the dwellers in Sheol are credited with the gift of making known their feelings of rejoicing at the downfall of the enemy. Sleep is their usual lot. Sheol is a horrible, dreary, dark, disorderly land, yet is the appointed house for all the living. Return from Sheol is not expected; it is described as man's eternal house. It is "dust"; hence in the Shemonah Esreh, in benediction No. II, the dead are spoken of as "sleepers in the dust." God's rulership over it is recognized. Hence He has the power to save the pious therefrom. Yet Sheol is never satiated; she "makes wide her soul," *i.e.* increases her desire and capacity. In these passages Sheol is personified; it is described also as a pasture for sheep with death as the shepherd. From Sheol, Samuel is cited by the witch of En-dor.

As a rule Sheol will not give up its own; they are held captives with ropes. The realm of the dead is in the earth, the gateway being in the west. It is the "land without return." It is a dark place filled with dust, but it contains a palace for the divine ruler of this shadow realm. Seven gates guard successively the approach to this land, at the first of which is a watchman. A stream of water flows through Sheol.

This concept of Sheol reverts to primitive animistic conceits. With the body in the grave remains connected the soul, as in dreams; the dead buried in family graves continue to have communion. Sheol is practically a family grave on a large scale. Graves were protected by gates and bolts; therefore Sheol was likewise similarly guarded. The separate compartments are devised for the separate clans, sects, and families, national and blood distinctions continuing in effect after death. That Sheol is described as subterranean is but an application of the custom of hewing out of the rocks, passages leading downward for burial purposes.

There is no scriptural basis for the belief in retribution for the soul after death; this was supplied by the Babylonians and the Persians, and received the Jewish coloring from the word "gehinnom" (the valley of Hinnom) made detestable by the fires of the Moloch. The smoke of the subterranean fires came up through the earth in this place; there are cast the spirits of sinners and blasphemers and of those who work wickedness and pervert the words of the prophets. Gehinnom has a double purpose—annihilation and eternal pains. Gehinnom has seven names: "Sheol," "Abbadon," "Pit of Corruption," "Horrible Pit," "Mire of Clay," "Shadow of Death," "Nether parts of the Earth." It is also called "Tophet." It has seven divisions, one under the other. According to rabbinical traditions, thieves are condemned to fill an unfillable tank; the impure sink into a quagmire; those that sinned with the tongue are suspended thereby; some are suspended by the feet, hair, or eyelids; others eat hot coals and sand; others are devoured by worms, or are placed alternately in snow and fire. These conceptions are ascribed chiefly to Joshua ben Levi, and have their parallel in the apocalyptic literature appropriated by the Christian church. The punishment of the evil endures twelve months, according to R. Akiba;

the generation of the flood will in time be released, but the punishment of those who have led others into heresy, or dealt treacherously against the law, will never cease.

The Garden of Eden is called the "Garden of Righteousness," being no longer an earthly paradise. It is above the earth, and its inhabitants are clothed with garments of light and eternal life, and eat of the tree of life in the company of the Lord and His anointed. In Slavonic Enoch its place is in the third heaven; its four streams pour out honey and milk, oil and wine. It is prepared for the "righteous who suffer innocently who do works of benevolence and walk without blame before God." It has been created since the beginning of the world, and will appear suddenly at the Judgment Day in all its glory. The pious dwell in those heights where they enjoy the sights of the heavenly "Hayyot" (previously mentioned) that carry God's throne. There are seven divisions for the good which shine like the sun, the moon, the firmament, lightnings, torches, and lilies. Each of these divisions is placed differently before the face of God. Each of the holy will have a mansion, and God will walk with them and lead them in a dance. As the wicked have a sevenfold pain, the righteous have a sevenfold joy.

"In the world to come there is neither eating, drinking, nor procreation, neither barter nor envy, neither hatred nor strife; but the holy sit with their crowns on their heads and enjoy the splendor of the Shekinah, for it is said: 'And they saw God, and they did eat and drink'; that is, their seeing God was meat and drink to them."

Regarding death, the philosophical attitude of the Jew is beautifully expressed in the following narrative:

During a brief absence of Rabbi Meir from home two of his sons died. Their mother, concealing her profound anguish, awaited the return of the father. He soon arrived, and after the customary exchange of greetings and a fond embrace she said to him: "My husband, some time ago, two jewels of inestimable value were placed in my charge for safekeeping. He who left them with me called for them this day, and I delivered them into his hands." "That is right," said the Rabbi, in an approving manner, "and I am very happy that you acted accordingly. Furthermore, we must always return cheerfully and loyally those things that are left in our care for protection." Shortly following this exchange in words the rabbi asked for his boys, and the heartbroken mother, taking him by the hand, gently guided him to the chamber of death. Meir gazed upon his sons and, realizing the truth, wept bitterly. "Weep not, beloved husband," said his noble wife; "didst thou not say to me we must return gladly when 'tis called for, and all that has been placed in our care for safekeeping and protection? God gave us these jewels. He left them with us for a time, and we gloried in their possession, but now that He calls for His own we should not repine."

The few following paragraphs are taken from the Talmud, which is replete with wit and wisdom:

The question is asked, "Why is a man born with his hands clinched, but has his hands wide open in death?" And the answer is: "On entering the world man desires to grasp everything, but when leaving it he takes nothing away."

Even as a fox who saw a fine vineyard and lusted after the grapes within the confines of the fence surrounding the enclosure; but being too fat to crawl through the only opening there was he was compelled to fast for three days. Having attained the necessary slimness it was an easy matter to gain access to the grapes. After having fed to his heart's content he could not get out until he had fasted for three days more. "Naked man enters the world, and naked does he leave."

Death is the haven of life, and old age the ship which enters port.

Do not speak ill of the departed, but remember that his soul still lives, though the body is dead.

It is our duty to comply with the last wishes of a dying person.

The death of the holy is a calamity equal in magnitude to the burning of the temple.

521 Pacific Avenue.

FURTHER CONTRIBUTIONS TO THE TREATMENT WITH DIGITALIS PREPARATIONS.

AN EXPERIMENTAL STUDY OF BLOOD PRESSURE AND TOXICITY.*

By ERNEST ZUEBLIN, M.D., F.A.C.P.,

CINCINNATI, OHIO.

ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF CINCINNATI; RESIDENT MEDICAL DIRECTOR, CINCINNATI BRANCH HOSPITAL.

Digitalis preparations for a long time were considered valuable remedies in the treatment of cardiovascular disease. While older colleagues are enthusiastic about its therapeutic effects, frequently we hear complaints from younger observers that this drug should be selected for special cases, and should not be used so frequently as was the custom in former years before we learned more about the occurrence of partial heart block and irregularities of the pulse rate due to an overdose of the remedy. If unexpected symptoms arise, is it the fault of the anatomical lesion, or is it the fault of the patient, or must the explanation be looked for in the particular nature of the remedy?

Without entering into the discussion of the first two questions, personal investigation has shown that the cardiovascular remedies are not constant in their physical properties; that they undergo changes as they become older, particularly as regards the ionisation studied by means of the fontactoscope.[1] It was found that notwithstanding a careful storage, excluding light and humidity, these changes take place. Furthermore, my investigations have revealed the possibility that, by exposing digitalis preparations to the action of high frequency waves, these drugs present a higher degree of ionization after such treatment. The question came up whether such drugs would gain in therapeutic efficiency by such a treatment.

To solve this problem the following experiments may be recorded.† It cannot be the aim of this pa-

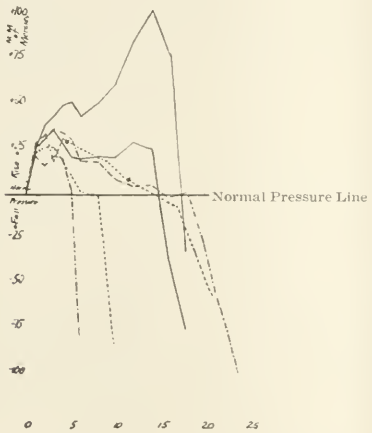
*Paper read before the Cincinnati Research Society, December, 1917.

†At this opportunity I wish to express my thanks to Dr. Coulsson, biological chemist at the Laboratory of Messrs. Sharp & Dohme, as through their courtesy the present investigations were carried out under my supervision.

per to report all the experiments made, but a few of them reviewed may be sufficient for the demonstration of their therapeutic differences.

The animals upon which the digitalis powder—crude and activated—was tried were cats, which, while kept under ether anesthesia when tracheotomized, had one carotid artery ligated and connected with the manometer filled with Ringer's solution, and the fluctuation of the blood pressure were recorded on the kymographion. The normal blood pressure was ascertained first for a period of at least 5 minutes. Into the femoral vein the test solution of either digitalin or activated digitalin solution of a given strength was injected, and the resulting changes in the blood pressure curve were studied until the death of the animal or until blood clot formation stopped the experiment. The lethal dose of the drug was calculated per one kilogram of animal weight.

Before entering into the discussion of our results let us consider the pressure curve* obtained by us-



ing digitalin dissolved in normal saline solution, one mil corresponding to .001 gram of digitalin.

Control animal, cat, male, weight 3.5 kg. Experiment begun on March 24, 1917, at 9.58 a. m., with normal pressure 166 mm., primary waves, 3 cm. in length, .3 cm. high, composed of two ascending and two descending wavelets measuring .1 15 cm. in height. Blood pressure 4 minutes later 163 mm., 3 mm. less when 2 mils were injected into the femoral vein. As a result we find a primary fall of 1.7 cm. after the injection, the maximum being reached at 1.9 c.m., the difference in height being .2 cm., which decline then is succeeded by a steep and prolonged ascent, the primary waves measuring .4 cm. in length and .4 cm. in height, the amplitude of the secondary wavelets being .3 cm.

Blood pressure at the beginning of the 6th minute registered 197 mm. or 34 mm. above the normal figure, at which moment 2 more mils were introduced into the femoral vein. A rapid drop of 1.2 cm. followed, which occurred at an earlier moment than before, and the average height of the secondary wavelets becoming less—.25 cm.—an unsuccessful attempt is made for a rise in the blood pressure, the drop in the pressure becoming more manifest, while the secondary wavelets reach an amplitude of .3—.35 cm. When 2 more mils of the test solution were introduced, the pressure reading at 7 minutes gave a lower figure, 181 mm., or only 18 mm. above the average normal value. A moderate rise of .3 cm. is the result with secondary wavelets not higher that .2 cm., irregular with groups of 4 wavelets and a more pronounced drop in the pressure curve composed of very shallow wavelets not higher than .1 cm. Following this, a steep rise of the pressure is observed to a higher level—20 mm.—while the primary waves become less pronounced and irregular in succession with small superposed wavelets not exceeding .1 cm. This rise is of short duration, since at the beginning of the 8th minute the pressure registered was 195 mm., ar 32 mm. higher than the average.

Two more mils of the test fluid injected were followed by no further rise, but by a drop of 12 mm., which occurred at an *earlier* period than in former observations. A blood clot in the carotid vessel observed at that time, though removed, complicated the experiment, so a further discussion of the curve is not attempted. It will be of interest to note that 15 mils of the test solution were required to kill the animal weighing 3.5 kg., or per kg. weight of animal 4.28 mils or .00428 grams of untreated digitalin in the course of 22 minutes were needed to produce the same result.

Since in the preceding experiment the formation of a blood clot did not permit any further discussion of the experiment beyond 6 minutes after the injection was given, I report another control experiment.

Control cat, male, weight 3.13 kg., examined on March 24, 1917. Ether anesthesia employed, tracheotomy done. Solution used consisted of digitalin —Merck—in normal saline solution, 1 mil corresponding to .001 gram of the original substance. Experiment started at 11.42 a. m., medium pressure for the following 4 minutes, 139 mm. No primary waves noticeable, the height of the secondary wavelets averaging .3 cm. With the introduction of the first 2 mils of test solution into the femoral vein a rapid but temporary drop in the pressure results, rapidly followed by a rise and a greater amplitude of the secondary wavelets, the height of which is .4 cm. The pressure has risen to 162 mm. 5 minutes after the start of the experiment, equivalent to a gain of 23 mm. The same amount of fluid injected is succeeded by a drop first in the pressure curve, which is compensated rapidly by a rise, the primary waves being just suggested, the secondary wavelets maintaining an amplitude of .4 cm., and 2 minutes after the first injection the pressure registers at 166 or 27 mm. above the normal.

Shortly after the repeated injection of .2 mils, a small depression in the pressure curve is noticed with a following attempt to reparation, but not reaching the former level. The primary waves are more manifest, with an amplitude of .3 cm. of the secondary wavelets. At the beginning of the next

*The pressure tracings cannot be reproduced, but instead a description of the changes observed on the records will be given.

minute the pressure shows the same level and a further injection is succeeded by a drop in pressure and more accentuated primary waves and with secondary wavelets the height of which is not in excess of .1—.2 cm. Four minutes after the injections were given we notice a fall in the blood pressure, namely, 158 mm., only 19 mm. above the average reading. Two mils injected results in a further drop of the pressure curve, presenting short primary waves and hardly perceptible secondary wavelets not exceeding .1 cm. in amplitude. Five minutes after beginning of the injection experiment the pressure curve has reached its normal level, the curve demonstrating an irregular rhythm and a hardly perceptible amplitude of the secondary wavelets.

Without any immediate injection 6 minutes after the start the pressure is just .2 cm. above normal and 1 mil injected produces a further drop and an irregular pulse curve, and the primary waves are not higher than .3 cm. in height and of irregular duration. Eight minutes after the onset of the experiment the pressure shows no improvement, just as if no further action of the drug could be expected. One mil of the fluid injected gradually is succeeded by an irregular, very accentuated curve, in which arrhythmia and extrasystole are suggested. Within 10 minutes after the beginning of the experiment the pressure curve registered a very low level, 56 mm. or 83 mm. below normal. One mil of test solution introduced results in a very rapid decline and no more secondary wavelets being encountered the animal succumbs a few seconds later. Thirteen mils being the lethal dose for the animal weighing 3.13 kg., or per kg. of animal weight, or corresponding to .004153 gram of untreated digitalin, with a treatment hardly exceeding 10 minutes.

In the animals which were injected with a solution of digitalin—Merck—which was subjected to the passage of high frequency waves the following pulse curves were obtained:

Test animal, cat, weight 2.65 kg., male, test solution 1 mil, corresponding to 0.001 gram digitalin, subjected to the high frequency waves, in normal saline solution—animal kept under ether anesthesia and tracheotomized. Experiment started on March 28, 1917, at 11.03 a. m. Mercury pressure for 3 minutes 155 mm., primary waves measure .25—.3 cm. in height, and consist of small crescendo and decrescendo wavelets, with an elevation of about 1 cm. After injection of the first 2 mils of digitalin solution into the femoral vein an immediate rise of .7 cm. is noticed, followed by a deeper depression and a steady ascent of the curve, with more pronounced primary waves and a longer amplitude of the secondary wavelets, measuring .2 cm. Three minutes after the beginning of the experiment the pressure is found at 182 mm. or 27 mm. higher. With an injection of 2 more mils the short rise is succeeded by a greater descent of the curve, which rises to a higher level, registering 186 mm., or 31 mm. more than at beginning of experiment. After another introduction of 2 mils a slightly more pronounced drop in the curve is noticeable, which then ascends to a higher level, while the primary and secondary wavelets show a higher amplitude. Three minutes after the injection the pressure has reached 191 mm., or 36 mm. above the normal readings.

The next dose of 2 mils injected coincides with a rise and a more accentuated drop of the pressure curve, succeeded by a lessened ascent, less marked primary waves and secondary wavelets of higher amplitude, measuring from .35—.4 cm., alternating with lower ones, which gradually lead to a lower pressure of 183 mm., or 28 mm. above normal at the beginning of the fourth minute. The fifth dose of 2 mils solution injected presents, after a small initial rise, a steady depression, an incomplete attempt to restoration and a smaller amplitude of the secondary wavelets measuring .2 cm. Five minutes after the first injection, the pressure curve registering 176 mm., or 21 mm. above normal, without any further injection, the primary waves became irregular and the secondary wavelets were further reduced to .1—.2 cm.

With six minutes' observation the pressure was at 175 mm., 20 mm. above the normal. One mil digitalin solution being injected the depression in the curve becomes more noticeable, also the primary waves are less marked, longer in duration, and very small secondary wavelets are encountered and only a slight increase of the pressure—22 mm. above normal—is noticed with 8 minutes' test. One mil injected results in a drop of the pressure curve, which slowly is compensated, the primary waves are less pronounced and the secondary wavelets again are very small. Ten minute pressure reading shows no difference in the former reading, and 1 mil more injected into the femoral vein results in a depression of similar depth as noticed before, with flattened primary waves, quite irregular in their registration.

Though with 12 minutes we notice a pressure of 185 mm., or 30 mm. in excess of the normal, the further dose of 1 mil coincides with a more accentuated drop of the primary waves and a decided irregularity in the height and succession of the same, with secondary wavelets barely noticeable. With 14 minutes the pressure reads 181 mm., or 26 mm. in excess of the normal figures. One mil of solution being injected the following drop of the curve is not restored to the former level, the irregularity of the primary waves, as to their height and succession, is still more noticeable. Sixteen minutes after the first injection the pressure has fallen to 120 mm., or found 35 mm. below the normal. The next dose of 1 mil, with a very irregular tracing, reveals only primary waves and 18 minutes' reading shows a pressure of only 80 mm., or 75 mm. below normal, when the last dose of 1 mil given results in the death of the animal 15 seconds afterwards. The lethal dose of the test animal found as 16 mils or 16 mg. of digitalin previously treated with high frequency current for 1 kg. of the weight of the cat would correspond to 0.00603 gram of the treated drug, acting over a period of 18 minutes.

Before entering upon the results of this experiment another instance may be given of a female cat weighing 2.24 kg. treated on March 28 in an identical way. Experiment begun on the etherized and tracheotomized animal at 2.57 p. m. Normal pressure for the first 3 minutes 87 mm., the height of the primary waves being .6 cm., the height of the secondary wavelets measured .2 cm. The first dose of 2 mils of the activated digitalin solution corresponding to 0.001 gram of digitalin in normal

saline solution, injected into the femoral vein caused a primary fall in the pressure curve, but was quickly followed by a rise to 113 mm. pressure or 26 mm. above the normal average in the first minute. The repetition of the same dose showed less marked primary waves, but a greater amplitude of the secondary wavelets, amounting to .4 cm. amplitude, the pressure curve at the end of the second minute having reached 125 mm. or 38 mm. above normal. The following pressure readings are obtained after 2 mils were injected up to the fourth minute. Third minute 131 mm., or 44 mm. above normal, and fourth minute 137 mm. or 50 mm. above normal. The primary waves are hardly noticed, the secondary wavelets become very marked by their amplitude of 5 mm. Five minutes after the first injection the pressure is found at 139 mm. or 52 mm. above normal.

The first indication of irregular waves is noticed, and the next injection of 1 mil is given within 6 minutes after the pressure had dropped to 44 mm. above the normal line. Irregularity of the primary waves and the small amplitude of the secondary wavelets was noticed, but still the ascent of the pressure curve to 138 mm. or 51 mm. above normal is conspicuous 8 minutes after the treatment was started.

The pressure readings are taken every 2 minutes and at the end of these notations 1 more mil of the test solution was injected. The varying length and the irregularity of the waves in their succession will be noticed, the secondary wavelets becoming smaller and hardly noticeable. The pressure readings at 10 minutes are recorded at 149 mm. or 62 mm. above normal; at 12 minutes, 173 mm. or 86 mm. in excess, the maximum being reached within 14 minutes, 191 mm. or 104 mm. above the normal level. The irregularity in rhythm and the tendency to drop occurring at that moment leads to a decided drop in the 16th minute, namely to 161 mm., being still 74 mm. in excess of the normal, and in the 17th minute with a pressure of only 55 mm., or 32 mm. less than normal the animal expires.

The lethal dose for this animal was found to be 16 mils of the solution, corresponding to .016 gram of activated digitalin, or calculated per kilogram of animal weight 0.00714 gram of digitalin acting for 17 minutes.

A comparison of the results with untreated and activated digitalin powder as recorded above may show the following possibilities, although we must bear in mind the individual differences in the animals used for comparison.

In taking control animal 1 the maximum pressure was reached in 6 minutes ofter the observation was begun or 2 minutes after the first injection, amounting to 197 mm. or 34 mm. above normal with only a slight difference in pressure after 4 minutes and after 8 mils of test fluid had been given.

Control animal 2 has reached its maximum pressure of 166 mm. or 27 mm. above the normal level in 2 minutes when 4 mils of the test solution had been administered and remained unchanged after the following dose.

For animal 3 receiving the activated digitalin product the maximum pressure was reached, namely 191 mm. or 36 mm. in excess of the normal 3 minutes after the first injection, and after the incorporation of 6 mils of test fluid, which result compares favorably with animal 2.

Test animal 4 has reached its maximum pressure 14 minutes after the first injection was given, showing an excess pressure of 104 mm., exceeding all previous observations. It will be noticed that already, in the second minute after the first injection with 4 mils test fluid was given, the rise in pressure is more marked than compared with the control animals.

From a perusal of the tracings we may learn that in the control animals the amplitude of the secondary wavelets diminishes more rapidly in height and occurs at an earlier moment than in the tracings referring to the instances when activated digitalin was given. Coincident with this fact we have observed an irregularity in the primary and secondary waves.

With reference to the toxicity of the genuine and activated digitalin products, it will be of interest to call attention to the difference revealed by the foregoing experiments.

Control animal No. 1 was killed in 22 minutes by a dose of 0.00428 gram; No. 2, in 10 minutes by 0.004153 gram; No. 3, in 18 minutes by 0.00603 gram, and No. 4 in 17 minutes by 0.00714 gram of activated digitalin powder, and such differences would suggest that the crude product is more toxic than the activated powder.

In the accompanying chart, containing also experiments with a solution of digitalin in the usual strength and then exposed to the high frequency waves, these differences in the physiological action are recapitulated. The full line indicating the activated powder shows, in comparison to the crude digitalin powder, that a higher blood pressure is to be expected which remains a longer period above the normal level at a time when the crude digitalin already presents its detrimental effects.

In presenting this study of digitalis remedies to the public, I am aware that more work has to be done to determine the physical and chemical changes which take place in these complex compounds, but as a preliminary communication, the subject appears to me of great interest.

Clinically speaking a few observations would suggest that cases of myocardial degeneration can be favorably influenced by subjecting cardiovascular remedies to the influence of the Herzian waves,[2] or by giving such cases a combination treatment of pharmaceutical remedies in addition to electric wave applications. From the chemical standpoint the proposition of changing the qualities of an organic substance by the exposure to electric waves is of interest, since my experiments have taught me that organic compounds are more susceptible to the action of wave energy, a conception which has been gained by experiments with ultraviolet light acting upon benzoic acid and iron compounds changing the first into salicylic acid (Neuberg).[3]

VACCINE DOSAGE IN THE ELIMINATION OF THE SYSTEMIC EFFECTS OF MOUTH INFECTION.*

By JOSEPH HEAD, M.D., D.D.S.,
PHILADELPHIA, PA.

VACCINE dosage is a problem that is being solved by accredited clinicians in a manner that theoretically might seem to altogether discredit vaccine therapy as a science. Initial doses of 500 million are given on the one hand, while other practitioners find that doses of one one-thousandth or even one ten-thousandth of these quantities gives satisfactory therapeutic results.

One cannot help feeling that the state of knowledge concerning the routine administration of vaccines is about the same as that held formerly in the routine administration of calomel or quinine, when these were first discovered and administered as drugs. Ten to fifteen grain doses of calomel were given, frequently with good therapeutic results, and then again salivation sometimes occurred under such dosage with permanent injury. In the same way quinine was frequently administered in fifty or sixty grain doses. When the patient was not sensitive to quinine unqualified good results were obtained, but when there was an idiosyncrasy disastrous if not fatal effects were encountered.

Some seven years ago when I began the treatment of my patients with vaccines I also used large doses. I gave myself experimentally forty-two weekly doses of vaccine, thirty-two of which each contained 1100 million mixed germs. The results were excellent. But during the first four or five years of my experience in this treatment I encountered very occasionally reactions in my patients so serious that at times I wondered whether the anxiety and worry occasioned made the treatment worth while. However, such satisfactory cures were obtained in 90 per cent. of the cases without any bad symptoms at all developing that there was more than sufficient encouragement to continue the treatment. Nevertheless, the result of my experience steadily impelled me to use smaller doses, so that instead of starting with a minimum dose of twelve to twenty-five million germs, or even fifty million, if the vaccine consists of four or five different species, I now start with doses of thirty thousand, and in some very exceptional cases this dose has to be reduced instead of increased. I believe that in a certain percentage of cases it will prove harmful to give a first dose of five to ten million germs until the tolerance of the patient is carefully ascertained. I do not desire to have an intense reaction as shown by depression, fever, acute or local inflammation, or marked variations in the blood pressure. I wish just to avoid these symptoms, and by so doing obtain better therapeutic results.

I am well aware of the incredulity that will be aroused by this statement since it is largely, if not entirely, based on clinical experience, but a little consideration may well show that it is not so preposterous as it may first appear. Webb has found that one or two tubercle bacilli when injected hypodermically are capable of giving excellent clinical results, and Myer Solis-Cohen, *Archives of Pediatrics, January*, 1918, has shown that one ten-millionth of a milligram of tuberculin residue may be an effective dose. If this is so, why then should the tubercle bacillus be absolutely in a class apart from all of the other organisms that infect the body? I have been growing cultures anærobically from material taken from the tips of extracted teeth. Formerly ærobic cultures alone were used but by the anærobic cultivation we appear to have discovered a new Gram-negative coccobacillus that is associated with the absorption of root tips, which germ seems to have extreme virulence and toxicity. And, as just stated, this new germ may partly but not entirely account for the reactions that occasioned the reduction in dosage.

It is claimed by many observers that certain people cannot advantageously take vaccine. This statement, when applied to autogenous vaccines, seems illogical, for, as a matter of fact, the patient by the mere presence of the disease has already taken the germs in a living state. I believe that any patient suffering from a localized infection can safely and usually beneficially take an autogenous vaccine prepared from the localized infection, if a judicious dosage is employed. And so again we come back to the question of dosage. The determination of the size of the dose depends primarily on the interpretation of what constitutes a preliminary reaction, and this interpretation is dependent upon a nice discrimination.

Seven or eight years ago the general procedure was to start treating a so-called normal patient with 12 to 25 million germs. If the patient showed depression or fever that did not last twelve hours the dose was doubled, and after a while it was again doubled, and doubled again, until incredibly large doses were given, the patient each time getting a terrific therapeutic bump. If the patient didn't get a bump the dose was increased, and if he did get a bump the dose was also increased, because it was noted by many authors and clinicians that those patients who had the worst reactions made the best recoveries. And so the rather loose philosophy of vaccine dosage seemed to be, "Give the patient small doses at first and increase them so as not to have too great a reaction, but if the patient does have too great reaction he will have a better recovery." Either way it's all right, and, strange to say, this vague unphilosophical theory of dosage seems ordinarily to have worked out very well.

The large doses administered gave good results and still do give good results in a great majority of cases but in a small though important percentage of cases they still do harm, and as the unfortunate results always make a greater impression than the good results it was not surprising that many physicians gave up the use of vaccines altogether. Many thousands of physicians were getting such good results, however, that the despairing cries from some esteemed leaders were not sufficiently conclusive to make them discard vaccines. Many of us felt too sure of the value of the treatment to be stampeded by crudities that must of necessity be remedied in the near future.

In my opinion there must be more investigation into the effect of small doses of vaccine. I still give my patients doses of one hundred and fifty million to three hundred million germs, but I in-

*Read before the American Association of Immunologists, March 30, 1918.

variably start with a small dose. I believe the average patient with his various latent infections is very much in the position of a many chambered magazine containing powder that must be touched off without blowing out the sides of the building. If each room of the magazine has small quantities of powder in it and the powder is slightly damp or slow burning the task is comparatively simple and one room at a time can be safely fired by a judicious explosive charge, but if there are an infinite number of compartments each full of explosive, and instead of slow-burning powder we have dynamite the difficulty is greatly increased and a much greater caution in the size of the explosive charge should be used.

I propose to recite briefly a few cases that have reacted in an astonishing way to small vaccine doses. There are many other cases that I could quote that unmistakably responded clinically to small doses but a mere piling up of cases would be tedious and unconvincing.

The first case was a man, aged 40, who had gouty deposits in the ears, crepitus and pains in the knee-joints, associated with sharp pains along the tendons of the thighs and legs whenever he walked—a typical case of systemic infection from diseased teeth and gums. The infected teeth were extracted and an autogenous vaccine was made. The first dose of 150 thousand germs made him uncomfortable, the second dose, a week later, of 210 thousand germs sent him to bed with inflammatory fever, painful joints, and swollen ears. After two weeks when the symptoms subsided a dose of 30 thousand germs was given that made his ears swell a little, but the dose was well borne. For four weekly intervals he was given 30 thousand germs, with marked improvement. Then he was given 60 thousand germs and promptly went to bed again, this time for only two days. Then 30 thousand germs were given at weekly intervals for six times and he made a most satisfactory recovery.

There are numerous cases where the patient showed marked improvement and also marked systemic reaction to weekly doses of 6 to 15 thousand germs, but I shall only mention one—that of a married woman, aged 36, of the systemic inflammatory type. Teeth sensitive to heat and cold, resisting all treatment. When she came for treatment she had just weaned her baby. The first dose of thirty thousand germs caused her breasts to become painful and to swell. There was also a vaginal discharge and she was depressed and ached all over. A week later she was given fifteen thousand germs with similar reactions but less marked, and these symptoms recurred seven times at weekly intervals, although the dose was reduced to nine thousand germs. The breast and vaginal reactions are particularly interesting as they could not have been the result of neurasthenia or hysteria. Meantime she showed marked improvement and the teeth were successfully treated and filled in a manner theretofore quite impossible.

The last case I shall mention is that of a woman, age, 62, who could not bear thirty thousand germs without a severe reaction but could stand fifteen thousand germs. Finally I tried sixty thousand germs as a test, and she had great depression and lymphatic enlargement especially in the groins. For two days she was so weak that she required cardiac stimulants.

In closing this paper it might be well to state my present method of ascertaining the proper vaccine dose. Thirty thousand germs are given at the start and raised by weekly doses so long as the patient bears the dose well, even if the dose goes up to a billion. However, when the patient is showing satisfactory improvement under a dose, that dose is maintained. If thirty thousand germs are not accepted easily the dose should be reduced to a number that are easily accepted. It is also especially important that the patient should be carefully watched for reactions.

When grip and colds are prevalent the patient who is given a dose that cannot readily be borne is apt to get sore throat or grip. Such an attack must be regarded not as an unimportant, accidental symptom, it should always be regarded as a possible reaction calling for dose reduction, and if the cold or grip should recur regularly with the vaccine administration, its recurrence should be considered conclusive evidence that the sore throat, cold or grip is a real reaction, calling for a corresponding modification in dosage.

It has been my experience that reactions occur in widely different forms and require most careful analysis on the part of the physician if the best results for the patient are to be obtained. It has also been my experience that large doses given at the start seem to mask a fine gradation of symptoms by which a just analysis of the patient's needs may be ascertained. Large doses may be accepted by the body because it is roused to combat a pathological assault, and being aroused, it protects itself and at the same time finds its energies exhausted, while the exactly ascertained dose that will just stop short of a reaction, philosophically may give the best therapeutic effect.

My vaccines are standardized by Wright's method controlled by turbidity tests.

Fifteenth and Locust Streets.

Goats in War Time.—Goats have decided advantage over other animals because they can shift for themselves. Even rabbits have to be provisioned. The goat costs practically nothing to keep and the return in meat, milk, etc., is highly advantageous.—*La Presse Médicale.*

Action of Sugar on the Bronchial Secretions.—Sanmartino having published the fact that injection of 1 gram of saccharose increases the amount of milk in the nursing woman, Lo Monaco adds that in a sufferer from bronchial catarrh the same injection causes a rapid diminution in the secretions and eventually arrests them completely. In tuberculous and bronchiectasis cavities the result is less pronounced. Lo Monaco sees here a great advantage over the use of expectorants, which are bound to cause anorexia and digestive disorders. The patient also gains the caloric value of the injected sugar. Injections into the muscles are recommended, although these are somewhat painful. The action of the sugar is simple—that of a vaso-constrictor. The author believes that in the earlier stages of tuberculosis sugar may exert a marked prophylactic action not only for the patient but for his entourage as well.—*Rivista Critica di Clinica Medica.*

Military Medicine.

Epidemic Cerebrospinal Meningitis.—Surgeon A. G. L. Reade, R.N.V.R., writing in the *Journal of the Royal Sanitary Institute*, February, 1918, says that previous to 1914 experience of cerebrospinal fever in Great Britain was mostly limited to sporadic cases and a few epidemics, the largest epidemic being in Glasgow in 1908. The unhygienic conditions, however, brought about by the mobilization and concentration of men in large naval military depots and camps favored an outbreak of the disease in epidemic form. Reade deals with an outbreak at the naval barracks at Chatham, England, and suggests the following methods of prevention: (1) Increased sleeping accommodation is a matter of the first importance. It was found that under the stress of mobilization the cubic air per man had been greatly reduced, sometimes to 320 cubic feet. The men were therefore thinned out by sleeping them in tents, drill shed, gymnasium, bowling alley, and gunnery school until more permanent tents were put up. These provided for the men to have, at least, 500 cubic feet per man, and since 1914 this has never been reduced and is the minimum that should be allowed. The ventilation was improved and supervised by frequent visits of a medical officer and a patrol of sick berth attendants during the night. (2) Disinfection. The room in which a case occurred was shut up, if possible, for two days. On the first day the windows, ventilators, fireplaces, etc., were closed up and formaldehyde vapor generated for twelve hours. The room was then washed down with izal solution and left to air for twenty-four hours. Meanwhile the bags and hammocks were disinfected. (3) Isolation of contacts. All immediate contacts were sent to hospital for bacteriological examination and in addition all men in the room were examined. (4) Frequent examination of men to detect carriers. With a large number of men it is impossible to examine them all, but it is hoped that in a short time all men will have their naso-pharynx examined before they are sent on draft. (5) Special care of delicate new entries. All new entries, boy seamen, boy servants, and stokers, are examined daily and any looking ill or anemic, or suffering from catarrh, are isolated in a special mess, are relieved from all duties, and generally cared for until their health improves.

In the discussion that followed the reading of Surgeon Reade's paper Dr. Alfred Greenwood said that greater stress should be laid upon bad ventilation in favoring infection, than upon cubic space *per se*. He had met with many instances where it was clear that bad ventilation of huts, caused through the deliberate blocking of ventilation openings by the soldiers, had been an important predisposing cause in the spread of cerebrospinal meningitis. Among scores of carrier cases, proved positive by bacteriological tests, he had never found one to develop the disease subsequently. Referring to preventive measures he said that as the germ of the disease appeared to be easily killed it seemed unnecessary to adopt elaborate, expensive methods of disinfection when a case had occurred, and a thorough wet cleaning of the room, with boiling of sheets, etc., would appear to meet the circumstances satisfactorily.

The Grave Form of Trench Foot.—In the *Medical Press*, April 8, 1918, Dr. E. Chanvin of the French Army discusses the grave form of trench foot. With regard to treatment he summarizes as follows: Finally tetanus forms one of the classic complications of frost gangrene. It developed in one of his cases, in spite of two preventive injections of serum. In presence of the array of serious complications, actual or prospective, therapeutic practice requires to be very energetic. The use of cardiac tonics, camphorated oil, caffeine, sparteine, general tonics, alcohol, quinine extract, general antiseptics, local applications, antimycosic treatment, or use of hot air, all these are but methods of expectancy. The neuritic structures must be got rid of sooner or later. Is it well to wait for spontaneous separation, and then have recourse to an economic trimming of the wound, or is it better to amputate early and save the patient from the grave risks which always attend the most skilled expectant treatment?

The ideal procedure would certainly be to await the separation of the eschar, while drying it up by application of hot air, and then embalming the part in pomades or antiseptic powders. After the separation to clean the stumps and asepticise it with appropriate dressings, and when we are at last in presence of a bone projecting from healthy soft tissues in a state of healthy granulation, to extirpate the projecting bone, and suture the edges of the wound. This is surely the method which enables us to preserve the maximum length of the affected limb, and it appears to us to be applicable in two groups of cases: (1) In those of congelation which are accompanied with grave general phenomena, but in which the sphacelus does not extend beyond the metatarsus. Here the tarsal articulations are intact. At the utmost, the tendons may infect their sheaths. There will be no deeply placed articular infection, and the maximum conservation of tissues can be secured, leaving the wound to be properly trimmed afterwards. (2) For the same reasons, this procedure should be adopted in the "massive" lesions which involve the whole foot and necessitate a tibio astragaloid separation. The narrow sectional plane above the ankle joint presents little liability to infection.

But in the intermediary types, where a groove of elimination has begun to form, a distant chopart or subastragaloid amputation should be promptly carried out; for temporization is, as previously said: (1) Dangerous. The separation of the gangrened extremity by no means marks the termination of the infective phenomena, and a grave septicemia may carry off the patient. Any or all of the complications already indicated are liable to appear. (2) Useless; the sole argument for its adoption being the prospect of securing a longer limb. But a secondary amputation, which is the form most frequently demanded in a highly infected case, must be carried out at a very high level on account of the propagation of purulent foci. On the other hand, on account of the progress of prothesis amputations of the leg are now preferred by a large school of surgeons to any of

the various disarticulations. Finally, early amputation, on the fourth or fifth day, as soon as the spachelus has become clearly defined, is as economic as the most obstinate and fortunate temporization; for it enables us to exterminate the dead tissues completely before the appearance of any secondary phenomena. Personally, Chauvain says, in their practice they have adopted early amputation in their later cases, after the disappointing experience of their first tentatives in conservatism. They have performed amputations of the leg, according to the extent and disposition of the lesions, either with an internal flap or, more frequently, a posterior one, reaching to a variable distance above the heel. A circular amputation, with reunion of the edges is often made necessary by the gravity of the local infection and enables the avoidance of operation at too high a level.

Bouchon's First Dressing.—Bouchon of the French medical corps contributes a brief article on his method of wound treatment to the *Journal de Médecine et de chirurgie pratiques* for March 25. He devised the technique two years before the war and described it at the London International Congress in 1913. It is adapted to recent wounds and amputation stumps and is practised only at the front. The wounded are then transported to a base hospital and on the fourth day, when the dressing is removed, the wound should be found clean and the patient without fever. The wounded man may be dressed in the trench, on the stretcher, or in the subterranean dressing station. In these advanced localities there is no opportunity for asepsis. The substance used for antisepsis and hemostasis is a solution of formol in alcohol and ether. One liter of equal parts of the two solvents contains 30 c.c. of 40 per cent. commercial formol and 3 gm. of methylene blue. Applied directly to the raw surface this solution is a powerful hemostatic and antiseptic. The dark clot which forms is not molested and behaves somewhat like an application of collodion. A compress soaked in the same solution is now applied and adheres intimately to the subjacent tissues; it is allowed to remain from three to six days. The method seems to be intended especially for amputation stumps in which suturing is not practised.

Antidysentery Inoculation.—Prophylactic inoculation against bacillary dysentery has, at last, promised to become a practical proposition. The organisms responsible for the disease known by this name are several and the difficulty has been to confer immunity against all these. The two main bacilli, those of Shiga and Flexner, have, however, furnished a vaccine, which in the hands of Captain H. G. Gibson, has given promising results. Neutralization of the toxins by means of eusol was unsatisfactory, it being found that such vaccine became toxic on keeping, due to the breaking down of the bacilli. Sensitized vaccines did not prove very satisfactory, as they failed to stimulate sufficiently the elaboration of protective substances. Gibson, thinking that the defect was due to antibacterial substances of the serum employed, which rendered the bacteria inert as antigens, absorbed these substances from the serum and administered the vaccine with this absorbed serum. Such vaccines produce little or no reaction and have been proved to develop protective substances in the blood. Trials are now being made in the field and it is hoped that these will be successful.—*The Prescriber*, April, 1918.

Canadian Hospital Bombed.—A despatch from London reports that on the night of June 24 the Germans bombed a Canadian Hospital and killed doctors, nurses, and patients. The Canadians have occupied the hospital for more than eighteen months. The roofs were painted with great red crosses and the buildings have never been used for military purposes. One operating staff, including the nurses, was buried under a mass of debris and in a few minutes the whole operating section was in flames. Bursting tubes of ether and hydrogen added to the horror of the scene. Two other surgical teams narrowly escaped, having just left a few minutes before to go to their midnight supper.

Big United States Hospital in England.—Work has been begun on what will be the largest military hospital in Great Britain. It is located near Southampton and will accommodate 3,000. The site is a country estate of 200 acres which the Red Cross has purchased. It plans to erect nearly ten acres of buildings. The contract provides for the opening of 400 beds within six weeks.

Fox Hills Hospital Ready.—The United States Base Hospital at Fox Hills, Staten Island, was completed on June 26. Eighty-six buildings have been constructed in 100 days. There are three large wards in the large buildings which contain 1,000 beds each. The transports will land their patients at Quarantine and they will then be taken to the hospital by motor ambulances. In connection with the hospital the Red Cross has built a theatre that will seat 7,200 persons. It is planned to have entertainment for the wounded soldiers and sailors every afternoon and evening. The Government has acquired fifteen acres of land adjoining the present site so that the capacity of the hospital can be doubled at any time.

Army Has Enough Dentists.—The War Department has authorized the statement that the dental requirements of an army of more than 5,000,000 men can now be met by the present force of the Dental Corps of the American Army. Examinations for dental officers have been closed and no more will be needed for at least six months. At the time that the United States declared that a state of war existed between this country and Germany, the total number of dental officers was 58. The present force now numbers 5,810. Commissions were offered to 5,467 dentists in all parts of the country and 95.1 per cent. were accepted, which speaks well for the patriotism of the dental profession. The Preparedness League of American Dentists which a year ago had a membership of 5,000 to-day has 15,000 members. This organization has been largely responsible for three dental ambulances that have been presented to the Surgeon General of the Army.

Army School of Nursing Endorsed by General Medical Board.—The committee on nursing of the General Medical Board has given its hearty sup-

port to the project of the Army School of Nursing and the facilities at the command of the committee will be used in a recruiting campaign to secure suitable candidates for the school. The plan of the Army School of Nursing will be based on the methods that have been found to insure the best care of the sick in civil life. The standard will be that of high class nursing schools, such as Johns Hopkins, the Peter Bent Brigham, the Lakeside of Cleveland, the Presbyterian, St. Luke's, etc. The plan provides that the headquarters of the school will be in the Surgeon General's office and the course of training will be given in the various base hospitals assigned as training camps, each one of which is to be a complete unit. The plan provides that the course leading to a diploma is to extend over three years. The experience in the military hospitals is to provide surgical nursing, including orthopedic, eye, ear, nose, and throat, and medical nursing. Experience in children's diseases, gynecology, obstetrics, and public health nursing is provided through affiliations with civil hospitals and visiting nursing organizations. It is expected that schools will be opened early in July at Camp Devens and Camp Wadsworth.

President Wilson Signs Rehabilitation Bill.—The bill providing for the vocational rehabilitation and return to civil employment of disabled soldiers and sailors has been signed by President Wilson.

Homes Offered as First Aid Hospitals.—At a committee meeting of the emergency unit of Harlem, New York City, on June 25, it was learned that H. C. Frick, George J. Gould, and S. Lewisohn have offered their homes to the Police Department as first aid hospitals in the event of an air raid or other emergency. The emergency unit is composed of physicians who are training to be prepared to give aid in case of emergency and are instructing those desiring to take lessons in first aid treatment.

Praise for Poets' Ambulance.—Arnaldo Fraccoroli, correspondent of the *Corriere della Sera* of Milan, writing from the Piave battle front, says that one of the most admirable episodes he has witnessed was the work of the ambulances inscribed "The gift of American poets." He says, "The courage of these young Americans doing their duty among the intense shell fire, this is indeed authentic living poetry."

Dr. J. Breckinridge Bayne of Washington, who was believed to be dead, is in a German prison camp. Dr. Bayne was serving with the British Red Cross in Roumania and when the Germans invaded that country and the rest of the hospital staff fled he remained behind to attend to the wounded and was taken prisoner by the Germans.

Americans in Fine Physical Condition.—At the weekly War Department Conference on May 25 members of the House Military Committee were told that the soldiers of the American Expeditionary Forces were freer from disease than the other armies and the troops training at home.

Dr. George F. Nicolai, formerly professor of pathology at the Berlin University and the author of a book denouncing Prussian Militarism for which he was punished by imprisonment, escaped from Germany in an airplane and landed safely in Denmark on June 24.

Mount Sinai Unit at the French Front.—The Mount Sinai Hospital Unit, designated as United States Base Hospital No. 3, has been established in a monastery near the front. On its staff are 26 officers, 65 nurses, 150 enlisted men, and several untrained women. The hospital has accommodation for about 1,500 patients. The surgical supplies are provided by Mount Sinai Hospital and the American Red Cross. The chief officers of the hospital are: Major Michael A. Dailey, commanding; Major George Baehr, Major Howard Lilienthal, Major Herbert L. Celler, Major Edwin Beer, and Major Walter M. Brickner.

Park and Tilford Donate Paris Offices.—The arrival of increased numbers of troops in France has created a need for greater hospital facilities. To assist in meeting this need Park & Tilford have donated their Paris offices to be used as war hospitals and for other war purposes.

Catholic War Council Builds Hospital.—Plans have been completed for the construction of a $300,000 hospital in Manhattan for soldiers and sailors by the National Catholic War Council. The site has been selected and arrangements made for the remodeling of one building and the erection of another. The hospital will have 500 beds, and immediately upon completion will be turned over to the Government to be used in whatever way the War Department deems best.

Give Home for Navy Hospital.—Commodore and Mrs. Morton F. Plant of Eastern Point, Conn., have given their large country home, the Watson House, to be used as a hospital for convalescent soldiers and sailors. The use of the residence is accompanied by a gift of $10,000 for its equipment.

Camp Upton Base Hospital Issues Publication.—The enlisted personnel of the Medical Department of Camp Upton are editing and publishing a four-page news issue under the title of "The Cure." It is "published in the interests of the base hospital rather often" with the "largest high grade hospital circulation in Camp Upton."

Osteopaths Not Admitted to the Medical Service.—At a meeting of the American Osteopathic Association in Boston, on Monday of this week, the president made a vigorous protest against the report made by the Surgeon General's Office to the Military Affairs Committee of Congress adverse to the acceptance of drugless healers in the Medical Corps of the army. He quoted from this report as follows: "The admission of osteopath physicians as such, and without the degree doctor of medicine, to the Medical Corps would have practically unanimous opposition of the medical profession of this country and of all allied countries; would be regarded, and justly so, as lowering the standards, educational and professional, of our Medical Corps, and would have a discouraging and detrimental effect upon efforts to secure physicians for the corps, both now and in future, and upon the general morale of the corps." It certainly is difficult to imagine how an osteopathic practitioner, who is forbidden by the license law to give drugs, could treat the wounded at the front or those ill with trench fever, or the like.

THE PATHOLOGY OF THE CARDIAC LIVER IN PULMONARY TUBERCULOSIS.

IF there is a well-established fact in relation to the tuberculous heart, it is certainly cardiac atrophy going hand in hand with the general emaciation. Whatever theories may be brought forward to explain the small size of the heart in phthisical subjects, it is, nevertheless, an established fact that the cardiac atrophy involves the entire muscle, and it may very well be that this general emaciation of the heart is the reason why the most trifling causes, acting on the weakened myocardium, result in dilatation of the organ. In cases in which the right heart gives way under pressure from the obstacle, the right ventricle is flattened and somewhat softened, and although the tricuspid valve is not involved in its integrity the auriculoventricular orifice is frequently dilated and insufficient.

Hypertrophy of the heart is met with in fibrous phthisis, particularly mitral stenosis, in chronic tuberculous interstitial nephritis, and when there is emphysema or pleural adhesion resulting in an increase of the heart work from respiratory difficulty. Under the term suprarenal asystolia Josué and Belloir have described a syndrome characterized by a considerable hypertrophy of the heart and a permanent drop in the maximum and minimum blood pressure. In these circumstances the liver was found to be of the nutmeg type and the suprarenal glands small, and markedly sclerosed, with tubercles in the apices, either cicatrized or undergoing evolution. It may be supposed that the suprarenal gland, after having undergone an exaggerated secretory function necessitated by the cardiac hypertrophy, finally gives out functionally, and there is likewise the possibility of direct action of the tuberculous process.

A number of writers admit the possibility of sclerosis of the myocardium during fibrous phthisis, due to the action of the tuberculous toxin, while fatty overcharge is quite as common. No matter what factor is in play, when hypertrophy follows dilatation of the right ventricle this is merely a transitory phase in the process, and when compensation does not take place dilatation of the right auricle and tricuspid insufficiency ensue. In other words, cardiac hypertrophy is the defense of the heart against obstacles; secondary dilatation indicates the impotency of the organ. This impotency reaches its maximum in tuberculous cardiac symphysis. Not only does the heart not increase in size, but it may even undergo atrophy. This process may occur without cardiac symphysis.

The explanations which have been offered for the small size of the heart in cardiac symphysis, in opposition to the production of pancarditis in rheumatismal symphysis, is the rarity of the coincidence of tuberculous endocarditis with symphysis, the slow evolution, the absence of myocarditic reaction, and the torpid inflammatory reactions in the surrounding structures. However, fibrocaseous or caseous nodules may be detected in the midst of the fibrous tissue; likewise gray granulations in the external leaf of the pericardium.

The external surface of the pericardium may adhere to the sternum and neighboring ribs, while adhesions may form between the mediastinal pleura and pericardium. The mediastinum may be transformed into a fibrous shell, in which case caseous lymph nodes will be found in the region of the hilum which have unquestionably played a part in the production of the surrounding fibrous tissue. On the other hand, the distribution of the neighboring fibrous tissue, that of the pericardial adhesions, is very variable, and for this very reason it is quite evident that one cannot give to cardiac symphysis a settled nosological value.

A cardiac liver in pulmonary tuberculosis has been merely mentioned as a possibility in fibrous phthisis. Nutmeg liver has been found in perhaps 1 per cent. of the cases. But the very special interest of a cardiac liver in tuberculosis is that it is accompanied by either fatty degeneration or cirrhosis. When the steatosis is slight it isolates the islands of localized blood stasis around the suprahepatic veins.

At the autopsy of tuberculous subjects no macroscopic hepatic lesion may be found, but in other cases, and these are the more frequent, the general aspect is that of a fatty liver. Occasionally, the viscus assumes a congested aspect, or one may find red islands of suprahepatic stasis, as in the nutmeg liver, which are here very distinct against the pale and yellowish background offered by a state of steatosis of the parenchyma.

But there are instances where the hypertrophy and congestion were marked, and on section of the hepatic gland the blood flowed out as in a typical cardiac liver where the fatty degeneration was so discrete that it was found only microscopically. This mixed condition of degeneration and congestion may be met with even in cases of tuberculous cardiac symphysis. But sclerosis may also be met with in these circumstances, and then it becomes the cardiotuberculous cirrhosis of Hutinel. The liver is hypertrophied and hard; it offers the nutmeg aspect, and upon section fibrous trabeculæ, sometimes visible to the naked eye, and decolorized areas corresponding to the steatosis, may be seen.

Histologically, islands of sclerosis around the suprahepatic veins and portal spaces are found, along with tuberculous follicles and fatty degeneration. And still more, perihepatitis, ascites, and various tuberculous peritoneal processes, are present.

INDUSTRIAL HEAT HAZARDS.

THE present day development of industries on a large scale has naturally created conditions of hazard which there has not been time yet either to study or to correct. That excessive heat produced in certain industries reacted badly upon the workers has long been noted, and recently Watkins (Public Health Reports, Vol. XXXII, No. 50) pointed out that these heat conditions and their effects are largely preventable, with the result that not only is the health of the worker improved, but the efficiency of the work is raised. The acute effect of excessive heat, heat exhaustion, is a comparatively minor consideration, because those who are so susceptible to it are soon eliminated from such occupations, but the chronic effects are the ones that create this industrial problem. To the heat hazard can be ascribed the general inefficiency of the worker, the loss of physical tone, and even a general physical deterioration, diminished resistance to fatigue, lowered resistance to disease, and a reduction of the period not only of usefulness but of length of life.

The heat production of the body being such an important function, it goes without saying that any vital interference with it must react badly upon the organism. The normal temperature of the body is maintained within rather narrow limits by the balance between heat production and heat loss. The production and the loss must be mutually proportioned, if not by one means, by another. In respect to heat loss, interference with one means usually provokes compensation by another. Body heat is produced by general muscular activity, gland activity, and the metabolic processes. All bodily energy is converted into heat, and about 80 per cent. of the food ingested is for heat purposes. Muscular activity is probably the greatest factor in the heat-producing mechanisms, and, of course, has an important bearing on the heat factor in the industries. On the other hand, body heat is lost by conduction, by radiation, by convection, by evaporation, and to a lesser extent by the excretions. But the loss of body heat varies particularly with conditions external to the body, and it is these conditions that industrial hygiene, with respect to the heat hazard, proposes to remedy. More than 80 per cent. of the body heat is lost by radiation, evaporation, conduction, etc., and these means are retarded or accelerated according as industrial conditions are appropriate. The relative humidity of the air, the temperature, the rate of air motion, all influence the heat loss. As the temperature of the air rises, the rate of heat loss or the transfer of heat from the body diminishes. Likewise, the loss of heat by evaporation diminishes as the humidity of the air rises. The relative humidity of the air is one of the most important factors in the heat hazard of industrial establishments. Much higher temperatures can be tolerated and much more heat lost when the relative humidity is within reasonable limits. About 15 per cent. of the heat loss is through evaporation—the water output of the body varies inversely with the humidity.

Most of the measures looking toward the eradication of the heat factor in the industries has to do with the engineering features, in the way of isolation of the source of heat or the separation of the worker from it. Much can be done, however, by attention to proper clothing, diminution of muscular activity to the minimum, appropriate diet, the water intake, bathing, and, above all, frequent rest periods to the workers by means of short shifts. It would seem that the removal of the clothing would aid the loss of heat, but in fact the presence of clothing which is saturated by perspiration is a great factor in heat loss, because moisture is so good a conductor of heat. The clothing should be light, and capable of absorbing moisture. Cotton would seem to answer the purpose, except for the fact that it allows cooling off so easily, and is therefore so likely to encourage internal congestion, with its possibilities. Wool does not have this objectionable feature, and woolen clothing is, therefore, best for this sort of work.

Provision for and the encouragement of water drinking is helpful in the dissipation of heat, but it must not be taken at a temperature below 55° F., because of the tendency to gastric disturbances. Frequent bathing with showers at a temperature of about 85° F. is very beneficial. In respect to food, it must be generally reduced in these occupations. Proteins and fats cause the greatest amount of heat production, and should be reduced. The starches, green vegetables, and fruits should be increased.

EFFECTS OF THE WAR ON THE FRENCH MEDICAL PRESS.

BARDET contributes an article on this subject to the *Bulletin Général de Thérapeutique* for February. He refers only to the medical press of France, but the periodical literature of the other warring countries, as well as that of some of the neutrals, is exposed to the same perils. From the very outset of the war the French journals have experienced great difficulties in getting out their issues. All of them ceased to appear for a few months, and not until the beginning of 1915 were certain among them able to reappear, but only a few on the original ante-bellum schedule. In regard to the *Bulletin* itself, it was hoped that two numbers could be issued monthly, beginning in January, 1915. This expectation was not realized, for two reasons. First, there was a great dearth of contributions, for the physician has time for neither writing nor research. Second, the printers are unable to issue more than one number a month. Scarcity of paper is a separate problem not included under the printer's shortcomings. The price of paper has quintupled since 1914. The amount of printed matter has been formally reduced by the Government, so that adver-

tising matter can total only one-third of the text proper. But without this outside intervention much the same results would come about from intrinsic factors already mentoned. The cutting down of advertising matter occurs despite the fact that the subscriptions of the readers fall far short of the cost of publication. Without its publicity columns, every medical journal in France would have to suspend. As it is, the subscription price may soon have to be doubled, and perhaps trebled. The publishers of medical journals will also be forced to withhold sample copies and exchange numbers. There has never been, with one or two exceptions, any profit in a medical periodical in France, and if publication must mean a total loss, then the outside world can no longer learn what French medical science is accomplishing.

Is Migraine a Radiculitis?

In migraine the presence of a meningeal reaction is but seldom alluded to by writers. Nevertheless, to this meningism may be attributed a number of migraine symptoms, such as flushing and pallor of the face, the peculiar pulse, photophobia, nausea and vomiting, and constipation. The tension of the cerebrospinal fluid is increased, and lumbar puncture often gives relief. These points are made by Babonneix and David in an article which appears in the *Journal de médecine et chirurgie pratiques* for March 10. The writers also note the hitherto undescribed symptoms of return of pain as a result of coughing and sneezing, and of aggravation of pain during the course of the paroxysm. This phenomenon has, however, been described in connection with radiculitis. If the brachial plexus is affected the severe arm pains following a sneeze are looked upon as pathognomonic. In radiculitis of the limbs the patients assume peculiar defense attitudes to minimize the effects of the sneeze. How explain the presence of this phenomenon in migraine? Is the latter a radiculitis of the trigeminus? In both migraine and radiculitis the increased tension of the cerebrospinal fluid may be a factor.

Typhus Fever in Paris.

Netter recently announced that a few cases of exanthematous typhus existed in Paris, which has not had a true visitation of the disease since 1893, although doubtless sporadic cases appear from time to time (*Journal de médecine et de chirurgie pratiques*, March 10). Two miserable children, brothers, covered with vermin, appeared to suffer from typhoid fever, but this affection was eliminated by hemoculture. It was then learned that two other children and the mother had the same affection, which was shown to be true typhus through guinea pig inoculation. Triboulet, another pediatrist, has seen a similar family epidemic. If it is granted that such cases occur in Paris, what is their source? We need not go as far as Africa, for in Brittany a sporadic incidence has been noted since 1893. Netter believes, however, that the metropolis has never been entirely free from the disease since the Middle Ages, but there is a constant tendency to attenuation of virulence and diminution of contagion. He then cites Brill's disease, first described in New York several years ago, and later in other American cities. His own cases, while perhaps not the same, are similar to Brill's disease. Much stress is laid in the Paris cases upon failure of attendants to contract the disease, and until this occurs, he says, the question of contagion does not become a vital one.

News of the Week.

Influenza Epidemic in Europe.—The epidemic of so-called Spanish influenza which recently incapacitated a large part of Spain is now in Paris and London and has also spread among the French and German soldiers. One report states that so many German soldiers have been incapacitated by this affection that it is delaying the drive that has been planned.

Conference on Vocational Education.—The Federal Board for Vocational Education, finding that the response to the request for a conference of the women interested in the supervision of the schools and the training of teachers under the Smith-Hughes Act for vocational education has been most gratifying, called a conference in Chicago, on June 26. The problems that have arisen during the year in the development of vocational home economics were discussed as well as plans for the carrying out of the program of part time and evening school instruction proposed as a war time measure.

American Association for Thoracic Surgery.—The first annual meeting of this association was held in Chicago, on June 10, 1918. The officers were: *President*, Dr. Samuel J. Meltzer, New York; *Vice-President*, Dr. Willy Meyer, New York; *Secretary and Treasurer*, Dr. Nathan W. Green, New York; *Councillors*, Dr. Edward R. Baldwin of Saranac Lake, N. Y., Dr. Rudolph Matas of New Orleans, La., Dr. Samuel Robinson of Santa Barbara, Cal., and Dr. Charles L. Scudder of Boston, Mass. An address was made by the president, Dr. Samuel J. Meltzer, and a "Review of the Evolution of Thoracic Surgery in the Past Fourteen Years" was presented by Dr. Willy Meyer. The treatment of empyema by the Carrel-Dakin method at the War Demonstration Hospital, the Rockefeller Institute for Medical Research, New York, was outlined upon invitation by Maj. George A. Stewart, M. R. C. "Remarks Concerning the Employment of the Dakin Solution in Cases of Empyema" were presented by Dr. Charles L. Scudder of Boston. As Dr. Scudder was unable to be present, the remarks were read by the secretary. A paper entitled "What Shall Be Done With the Open Chronic Suppurations of the Chest Cavity?" (with presentation of patients) was read by Dr. Emil G. Beck of Chicago. "Post-Operative Thoracic Drainage" (exclusive of empyema) was the topic for discussion. The discussion was opened by Dr. Nathan W. Green, continued by Dr. Willy Meyer and Dr. Conrad Georg, Jr. Dr. B. Merrill Ricketts of Cincinnati presented many *x*-rays of partial and complete pneumothorax. A film of the skin sliding operation was presented by Dr. Emil G. Beck of Chicago. The following officers were elected for the ensuing year: *President*, Dr. Willy Meyer, New York; *Vice-President*, Dr. Henry S. Plummer, Rochester, Minn.;

Secretary and Treasurer, Dr. Nathan W. Green, New York; *Councillors*, Dr. Samuel J. Meltzer, New York, one year; Dr. Rudolph Matas, New Orleans, two years; Dr. Samuel Robinson, Santa Barbara, Cal., three years; Dr. Charles L. Scudder, Boston, Mass., four years. The association has a membership of seventy-one at the present time.

American Medical Editors' Association.—The forty-ninth annual meeting of the American Medical Editors' Association was held at the La Salle Hotel, Chicago, on June 10 and 11, under the presidency of Dr. George W. Kosmak of New York. One of the features of the meeting was the banquet on the evening of June 11, at which time Colonel R. E. Noble, M. C., U. S. A., spoke on the needs of the Medical Service; the Hon. Quinn O'Brien made an address choosing as his subject, "Is America Doing Her Best?" Colonel Charles Dercles of the French Army and A. Franklin Martin also made addresses. At the Executive Session resolutions were passed remitting the dues of members of the Associtaion who were in the service. Other resolutions adopted placed the organization on record as in favor of the Owen-Dyer bill and also in favor of granting appropriate insignia and rank to women physicians who were giving war service equivalent to that of the men physicians. The Association relected its present officers for another year. They are Dr. George W. Kosmak of New York, president, and Dr. Joseph MacDonald, Jr., of New Jersey, secretary and treasurer.

Physician Visits Convention in Airplane.—Captain H. M. Strong, M. R. C., Post-Surgeon, Chanute Field, Rantoul, Ill., made the trip to Chicago to attend the meeting of the American Medical Association in an aeroplane. This is the first known instance of a physician being so anxious to get to Chicago that he could not wait for train or trolley.

Cornell University Confers Degrees.—The commencement exercises of the Cornell University Medical College took place on June 12, at which time the degree of Doctor of Medicine was conferred on thirty-two students. Major Charles L. Gibson made the address to the graduating class. Nine of the graduates have received commissions in the United States Navy and have entered the service.

Ask Government to Stop Disorganization of Hospitals.—The Hospital Conference of the City of New York recently passed a number of resolutions among which was one advising that arrangements be made for the training of a large reserve of non-professional nurses. It was also resolved "that the President of the United States be urged to take such action as in his judgment will preserve the hospitals of the country from the further disruption of their organizations and the abandonment of their indispensable public tasks."

Opposition to Medical Enlistment.—At the annual conference of the Health Officers of New York State, Dr. Hermann M. Biggs, State Health Commissioner, according to newspaper reports, expressed the opinion that physicians should remain at home in sufficient numbers to care for the civil population rather than to enlist except upon special demand for their services. He emphasized the fact that no nation can produce a fit army unless its people are fit.

Dinner in Honor of British Doctors.—About fifty physicians of New York City gave a farewell dinner at the Metropolitan Club, on the evening of June 25, to Sir William Arbuthnot Lane, Sir James Mackenzie, and Colonel Herbert A. Bruce on the eve of their departure for England. All three of these men made brief addresses.

Dr. Edward H. Bradford, for six years dean of the Harvard Medical School and connected with the teaching staff for thirty-eight years, has resigned.

Dr. David Linn Edsall, since 1912 Jackson professor of clinical medicine in the Harvard Medical School, has been appointed dean of that institution in succession to Dr. Edward H. Bradford.

Dr. Walter James of this city has been appointed chairman of the new commission for the feeble-minded, which body, under an act of the last legislature, became effective July 1.

Dr. Samuel E. Fletcher of Chicopee, Mass., has been appointed medical examiner for the Fifth Hampden District.

Dr. Martin S. Budlong of Providence, R. I., has been appointed to the State Board of Health of Rhode Island to fill a vacancy caused by the death of J. Hillman Bennet.

Dr. Joseph S. Neff, formerly Director of Public Health and Charities of Philadelphia, has been appointed by Governor Brumbaugh a member of the Advisory Board of the Pennsylvania State Department of Health.

Dr. Elmer H. Funk has been elected Medical Director of Jefferson Hospital of Philadelphia, succeeding Dr. Henry K. Mohler, who has entered the military service of the United States with the Jefferson Base Hospital Unit No. 3.

Another Anthrax Patient Cured.—A patient who was operated on for anthrax at Bellevue Hospital, New York City, on June 14, was discharged as cured on June 29. This is the fourth of a series of eleven cases of anthrax treated successfully at Bellevue Hospital.

The New York and New England Association of Railway Surgeons will hold its twenty-eighth annual session at the Hotel McAlpin, New York City, on October 21, 1918. A symposium will be presented on the Modern Treatment of Infected Wounds. The president of the association is Dr. J. S. Hill of Bellows Falls, Vt., and the secretary is Dr. George Chaffee of Little Meadows, Pa.

Medical Society Elections.—The MAINE MEDICAL ASSOCIATION, at its meeting in Portland, on June 7, elected the following officers: *President*, Dr. George H. Coombs of Waldoboro; *First Vice-President*, Dr. John Sturgis of Auburn; *Second Vice-President*, Dr. Charles W. Bell of Strong; *Secretary and Treasurer*, Dr. B. J. Bryant of Bangor.

The MAINE HOMEOPATHIC MEDICAL SOCIETY, at its meeting in Bangor, on June 11, elected the following officers: *President*, Dr. F. A. Ferguson of Portland; *First Vice-President*, Dr. W. A. Ratters of Pittsfield; *Recording Secretary*, Dr. E. S. Abbott of Bridgton; *Corresponding Secretary*, Dr. Carrie E. Newton of Brewer; *Treasurer*, Dr. W. S. Thompson of Augusta.

The California State Homeopathic Society, at its annual meeting in San Bernardino, on June 5, elected the following officers: *President*, Dr. M. W. Kapp of San Jose; *First Vice-President*, Dr. H. A. Atwood of Riverside; *Second Vice-President*, Dr. Anna D. Chapin of Los Angeles; *Secretary*, Dr. Guy E. Emming of San Francisco; *Treasurer*, Dr. T. C. Low of Los Angeles.

The South Dakota State Medical Association, at its annual meeting, held at Mitchell on May 24, elected the following officers for the ensuing year: *President*, Dr. D. L. Scanlon of Volga; *First Vice-President*, Dr. H. T. Kennedy of Pierre; *Second Vice-President*, Dr. G. S. Adams of Yankton; *Secretary-Treasurer*, Dr. R. D. Alway of Aberdeen.

The Vermont State Homeopathic Medical Society held its annual meeting on May 30, in Montpelier, and elected the following officers for the coming year: *President*, Dr. E. D. Kirkland of Bellows Falls; *Vice-President*, Dr. G. E. Morgan of Burlington; *Secretary*, Dr. G. I. Forbes of Burlington; *Treasurer*, Dr. F. E. Steele of Montpelier.

The Maine Medical Association, which held its annual meeting on June 7, elected the following officers: *President*, Dr. C. M. Coombs of Waldoboro; *Vice-Presidents*, Dr. John Sturgis of Auburn and Dr. Charles W. Bell of Strong; *Secretary and Treasurer*, Dr. B. L. Bryant of Bangor.

Obituary Notes.—Dr. Thomas Cook Stellwagen died of diabetes at his home in Media, Pa., on June 7, aged 76 years. He was a graduate of the Medical Department of the University of Pennsylvania, in 1868, a Fellow of the Philadelphia Academy of Surgery, and formerly a professor in the Philadelphia Dental College and the Dental Department of the Medico-Chirurgical College.

Dr. A. I. Holsonback, a graduate of the Maryland Medical College, in 1860, died at his home in Graniteville, S. C., on June 8, aged 88 years. He formerly practiced medicine in Augusta, S. C.

Dr. M. Osborne Christian, a graduate of the Harvard Medical School in 1878, died at his home in Irvington, N. J., on June 15, aged 69 years. He was connected with the Geological Survey and the Smithsonian Institute.

Dr. Frank Chase Richardson, a graduate of the Boston University School of Medicine, in 1879, died in Roxbury, Mass., on June 20. He was for many years professor of neurology at the Boston University School of Medicine.

Dr. J. Hervey Buchanan of Plainfield, N. J., a graduate of Jefferson Medical College, in 1896, a Fellow of the American Medical Association, and a member of the Medical Society of the State of New Jersey, died on June 11 at the age of 45 years.

Dr. Gwilym G. Davis of Philadelphia died of pneumonia at Kineo, Me., on June 16, aged 61 years. He was a graduate of the Medical Department of the University of Pennsylvania in 1879, and later professor of orthopedic surgery in that institution. He was a Fellow of the American Surgical Association and the American College of Surgeons, a member of the American College of Clinical Surgeons, the Pathological Society of Philadelphia, the Philadelphia Pediatric Society, and other medical organizations. Dr. Davis was surgeon to St. Joseph's, the Episcopal and the Orthopedic hospitals, and to the Children's Seashore House in Atlantic City.

Correspondence.

ROTARY MICROTOMES DESIRED FOR THE ARMY.

To the Editor of the Medical Record:

Sir:—At the present time there is a considerable scarcity of rotary microtomes, and a marked need for them at the various camps, where it is desired to make pathological examinations of lung tissue in differentiating the broncho from the lobar pneumonias. A number of the firms who formerly made this apparatus are now working on signal corps and ordnance material, and we are, therefore, handicapped.

Might I ask you to make a request through the columns of your paper to the effect that the Medical Department is anxious to purchase a number of rotary microtomes for use on paraffin sections? Any one having a rotary microtome to dispose of should communicate with me at the address given below.

I prefer not to borrow these instruments, as I would have to assume a responsibility for instruments which would pass out of my possession, and misunderstandings would doubtless occur.

M. A. Reasoner,
Lt. Colonel, Medical Corps, N.A.

Field Medical Supply Depot, U. S. Army, 21 M Street, N. E., Washington.

WOMEN PHYSICIANS AND WAR SERVICE.

To the Editor of the Medical Record:

Sir:—It ought to be a matter of regret that the admirable qualities now being displayed by women, and causing such unbounded surprise by their unexpected presence, were not allowed expression before, for the qualities referred to are always desirable and necessary. Women's present response to opportunity is a frequent topic of discussion. The medical women in the countries of our allies found it necessary to create even the opportunity.

The Women's Hospital Corps, now established in the big military hospital of 600 beds in Endel Street, London, found their proffered service refused by the British Government in 1914, and it was not until this organization of women surgeons had demonstrated their ability in caring for wounded and dying Frenchmen that Britain invited them to return home to care for their own wounded. The surgeon in charge of the Endel Street Hospital is Major Louisa Garrett Anderson, daughter of the second woman physician of modern times. Every member of Dr. Anderson's staff is a woman, and from the battlefields across the Channel ambulances of wounded men are brought to her and her aides to patch up and make over again.

While in France the W. H. C. cared for wounded Tommies as well as Frenchmen, and it was said by one of them to Sir Alfred Keogh that word was abroad in the trenches that when a man was wounded the Woman's Hospital was the place to go to; "that women surgeons took more pains, and were less hasty about cutting off legs and arms, and that the women were quite all right."

Another organization of British women is known as the Scottish Women's Hospitals, and it has won for itself world-wide fame. This organization was

in charge of Dr. Elsie Inglis, who aimed to place a hospital wherever it was most needed. She has had as many as twelve operating simultaneously. These hospitals have had service on five battle fronts. It has sometimes been necessary to pack up the equipment and retire with the retreating army. They have even been captured. One of them, on its way to Serbia, was requisitioned by the British Army at Malta to aid in caring for the wounded being brought in from Gallipoli. When they departed the military authorities at Malta wrote home for sixty more medical women to be sent to them; and when the Home Office read the report which accompanied this request they decided to send sixty to Malta and eighty more to other military hospitals.

One of the Scottish Women's Hospitals in the Rue Archimède, Calais, in charge of Dr. Alice Hutchinson, had the lowest percentage of mortality in typhoid fever of any hospital in France. Another of these hospitals at Troyes, in charge of Dr. Louise McElroy, was one of the few hospitals to receive official command to pack up and proceed to Saloniki to be regularly attached to the French army, furnishing one of the few instances where a voluntary hospital was so honored.

The S. W. H. faced almost insurmountable difficulties in Serbia. They braved dirt, infection, and cold; they found it necessary at times to carry the wounded themselves, and their endurance was put to the most severe tests. The chief of the Serbian command said of them: "Their capacity for work and for suffering seems incredible, and while they equal the Serbian soldier in endurance, in morale no one is equal to them." Dr. Inglis led an army herself through frozen passes in Serbia and Russia to safety a short time before she yielded up her life in the service of humanity.

The French woman physician has also been winning laurels. Dr. Gerard-Mangin became an army doctor by stratagem, and necessity caused her services to be retained until she had proved her value. In the first three months of her service she performed six hundred open operations without losing a single patient. She afterward established a temporary hospital at Verdun, where she was under fire for seventeen months. At first, her hospital was without equipment or convenience, and she was almost destitute of assistance. For six weeks her clothes were not once removed from her body. One of her feet was frozen. A man was shot at her side one day, and she was slightly wounded. This woman was recalled from the front to take charge of the Hôpital Militaire Edith Cavell, in the Rue Desmouettes, Paris, for Dr. Gerard-Mangin is an expert in tuberculosis. The rank of major has been conferred on this little, rosy-faced expert. Dr. Gerard-Mangin did a two-years' service at the front without an hour's absence from her post, and she is the only surgeon in the French Army of whom this statement can be made.

Women physicians of the allied peoples have by their professional ability, initiative, resource, energy, and endurance won from reluctant governments a recognition long denied them, to the prejudice of the people who might have been benefited by their ministrations. Women are now in charge of big London hospitals, where formerly no woman was permitted on the staff. Five of these hospitals are entirely staffed by women. Women have demonstrated over and over again professional skill and ability of the highest order, and during the four years of the World War no woman has ever been dismissed for professional incompetency or physical disability.

Britain's change of heart on the woman-physician question has been so complete that she is now urging her eligible women to study medicine, and is even providing, when necessary, funds for this purpose, and an increased number of women medical students is now found in the medical schools. American women physicians are capable of rendering aid as valuable as that given by their sisters abroad. Over 33 per cent., we are told, have already gone to the front or registered for war service.

Although it is but a short time since we began to participate actively in the war, the shortage of physicians has grown markedly and is bound to increase. The fact that fewer students are entering medical colleges will, in the not far-distant future, still more affect the shortage. As, on account of the draft, women are available in larger numbers than men for medical study, eligible women should be urged to take up the study of medicine in order to be ready when the need for them arises. It is an error of judgment, as well as an economic waste, to urge women eligible for entrance to the higher professions to take up nursing, for the nursing material is relatively abundant, while the pre-medical material is not. Physicians are needed quite as much as nurses, and are more valuable and more difficult to secure.

It goes without saying that rank and salary should depend upon ability and service and not upon sex. It is a travesty on democracy to fight autocracy with one hand and carefully shield it with the other, as we so often do. That Prussian attitude should be swept away to make a place for the square deal to which every American citizen has a right. When burdens are laid without stint upon *all*, privileges should be dealt out equally.

A committee of the Women's Medical Association of New York City has been formed to encourage and assist eligible young women to take up the study of medicine as a patriotic duty, and the broad-minded physician who realizes the country's need cannot do better than assist in this worthy object.

Maude Glasgow, M.D.

171 East Eighty-third Street.

PRESCRIPTIONS FOR VENEREAL DISEASES.

To the Editor of the Medical Record:

Sir:—The result of the recent amendment to the public health law to which the State Commissioner of Health has publicly called attention will be to hamper, if not to penalize, both doctor and druggist in their professional relations with patients using medicinal agents which may be construed to be remedies for venereal disease. Already the New York State Department of Health has made itself, under the law, the sole executant of the right to advertise either remedies or forms of treatment for

these diseases, even to the exclusion of reputable medical journals. It has even gone so far in this respect as to appropriate the publicity privileges hitherto exclusively enjoyed in public lavatories by quacks. If this be a form of "public service" at the expense of the taxpayers, the sooner it is proclaimed from the more reputable places, now so generally impounded for public service of all character, the better. As a friend and well wisher, no less than a coworker with the members of the profession of pharmacy, I would advise them for their self-protection to disregard certain provisions of this law. For a druggist to refuse either a copy of a prescription or to renew a prescription containing a remedy for venereal disease, unless ordered to do so by the physician, is to stigmatize those presenting such a prescription for compounding which may have no such purpose. This is an act for which the druggist could be held responsible, as tending by implication to degrade the purchaser with whom he is dealing. Both by the ethics of his profession and by the law the druggist is not to take cognizance of the character or purposes of the remedies he dispenses, or to use the knowledge thus gained, except under process of criminal law when compelled to do so by the court.

If the law under consideration demands this service it should be exacted of the physician, not the druggist. The latter alone can decide whether his prescription is intended for a case of venereal disease. This the framers of the law could not demand of the physician, but they felt from past experience that they could accomplish the same purpose by making a cat's paw of the druggist. Before the druggist thus discriminates he should demand this protection from the doctor, in writing, on his prescription. Despite the threats and penalties held over his head by the State Department of Health, his refusal otherwise to stigmatize this one class of patients would be upheld by any court or jury in this State.

JOHN P. DAVIN, M.D.
117 W. 76TH STREET, NEW YORK.

STUDY OF CEREBROSPINAL LOCALIZATION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I should like to suggest a determination of the distribution of cerebrospinal lesions and localization of structural changes by the study of vascularity through injection of blood and lymph vessels. The method has, to my knowledge, been applied to the study of lesions in various organs, as, for instance, the kidney and liver. Injections very frequently show in these organs the vascular changes and their localization, and even permit of a quantitative estimate of them and a comparison of vessel and tissue volume. The work is of distinct interest and value.

It certainly seems that in the case of an organ such as the brain or cord, in which each unit plays an important part, and vascularity is of the highest importance, the same method must yield results equally interesting and of real interest. In point of fact, I have seen very little in the way of reports on such work.

Results are certainly to be expected in sclerosis, such as multiple sclerosis and the atrophies, and vascular scleroses, such as senile psychosis and arteriosclerotic conditions. Such work must also throw light, whether the results be positive or negative, upon the wide array of psychoses, choreas, epilepsies, etc., which invite pathological investigation.

Such work, when correlated with clinical material, would afford a method of cerebral and cord localization. If, by chance, it affords any knowledge of unmapped areas, the time spent at it might even be regarded as entertainingly spent.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE CALLING UP OF MEDICAL MEN FOR MILITARY SERVICE—A NEW MEDICAL DIRECTOR IN FRANCE—TRENCH FEVER INFECTION—HONOR FOR HARVEY CUSHING.

LONDON, June 13, 1918.

MEDICAL men, though liable, of course, to ordinary conscription, practically are never taken now for purely military service, the gross waste of scientific material implied in such an action being fully recognized. It being on all hands allowed that the right duties for a medical man to perform are medical duties, the question of exemption from medical military service has to be decided on two grounds only: (1) Is the medical man physically able to undertake the responsibilities which a commission in the army may entail? And (2) is the medical man, exemption not being claimed on physical grounds, doing more valuable service to the state by remaining in a civilian capacity than could possibly be expected from him if he were with the colors? A Central Tribunal decides questions of exemption for the whole country and for all classes, but it is in the nature of a supreme appeal court, and so far as medical men are concerned is asked to give no decisions until every individual case has been thoroughly sifted by bodies chosen for the purpose. Regulations or instructions which have been recently published dealing with applications by medical men for exemption make it possible that this central tribunal will have more work to do, especially as the Ministry of National Service is considering the whole question of man power in the country and its proper employment. The new instructions which have just been issued with reference to the calling up of medical men institute a special medical tribunal to which in future all applications for exemption are to be made, but this tribunal is simply "The Local Arrangements Subcommittee" of the Central Medical War Committee renamed "The Medical Tribunal." In my letter of February 23* I explained the elaborate constitution of the Central Medical War Committee and its affiliated bodies, to whom the recruiting of the medical profession have been intrusted by the War Office almost since the outbreak of hostilities. As each area of the country now comes under review, notification will be sent by the Ministry of National Service to the practitioners affected, informing them of the time within which they may apply for exemption if they desire it. The Medical Tribunal, in association with the Committee of Reference of

*MEDICAL RECORD, March 16, 1918, p. 469.

the English Royal Colleges will give every applicant for exemption an opportunity of being heard before a report on his case is made, and if it is decided by the Medical Tribunal that it is the duty of a medical man to accept a commission, he can still appeal to the Central Tribunal, like any other citizen, on grounds of serious hardship, of ill health, or of conscientious objection. But it is not intended that cases should come before the Central Tribunal unless important questions of principle are involved or unless some special reason can be fairly alleged. The Medical Tribunal is representative, through the various local war committees of the Central Medical War Committee, of the whole of the medical profession of the country, and is now in possession of full and detailed information of the professional position of every medical man on the register, and of the local professional needs of every area. The Committee of Reference which acts with the Medical Tribunal has been selected by the Royal Colleges in order to deal with the institutional needs of various areas. It is the duty of this body to provide that the hospitals, general and special, and all infirmaries shall not be unduly depleted of their medical officers, and along these lines the work of the Committee of Reference is partially military, for there is not one of these institutions which has not since the outbreak of war put its beds and the services of its honorary staff at the disposal of the sick and wounded of the war. The demand for medical practitioners is now so great both for military and civilian purposes that it is only by carefully considered distribution of the available medical men that the requirements of the country can be met. The special position of the medical profession has been recognized by granting its members, for exemption purposes, a court composed of themselves. Great trust in the patriotism and bona fides of the profession has thus been shown by the nation, and the result in times of unthinkable stress has been on the whole satisfactory. The new instruction will be administered consistently with the national interests, but with a consideration for particular medical cases which could not possibly have been extended to candidates for exemption by any tribunal composed of laymen.

At a moment when the German offensive has recommenced with particular vigor against sections of the Western line held by British troops, either alone, or in conjunction with the American contingents, the retirement of the Director General of Medical Services on the Western Front appears to be inopportune. Sir Arthur Sloggett has been the Medical Director General in France since the outbreak of the war and although he has reached the age limit for active service, there are undoubtedly many who would have liked to see him remain at his post during these particularly critical times. He has discharged his manifold and far-reaching duties well, he has been quick to see where developments were needed and willing to trust the right men to carry them out. He has made intelligent use of the different branches of expert medical service which have been placed at his disposal; and—crowning distinction for an officer in a supreme position—he has earned the reputation of fairness in his various selections and promotions. Lieutenant General Burtchaell who succeeds him has, it will be admitted, the strongest possible claims to the office which circumstances have made vacant. He is at home with army administration in the War Office and in foreign lands both in times of peace and times of activity. He has been a staff officer in Indian Commands and in the South African War. He has had an appointment under the Irish Command, and for the period immediately preceding the war he was employed by the War Office as Assistant Director General of the Army Medical Service. Since the war broke out General Burtchaell has been in France and closely associated under Sir Arthur Sloggett with the reorganizations required to meet the needs of a growing army. In this way to a knowledge of the medical needs of the British soldier he has added close association with the Over-seas Forces—American and Colonial—to whom his appointment is noticeably welcome. His appointment to the supreme command on the Western Front at this juncture of the war will entail upon him immense responsibilities, but his record shows that he will be able to meet them and that he can rely upon the hearty cooperation of his professional colleagues.

Trench fever, after having been identified under a good many names and after the name had been applied to a good many varying conditions and phases of numerous diseases, is now recognized as an entity and the latest investigation carried out on behalf of the War Office has thrown light on the mechanism of its infection. The work has been carried out by Major Byam, Captain J. E. Carroll of the United States Army Medical Service, Captain Lyn Dimond, and an enthusiastic band of volunteers and the result is an important chapter in the epidemiology of parasite-borne disease. Lice as carriers of the infection had been identified, of course, long before this latest investigation was undertaken, but some points have now been established of great scientific interest. The voluntary workers, to whom allusion is made, were the subjects who submitted themselves to the bites of infected lice, and the first point established was that trench fever could not be produced by the bite alone of infected lice. One man who received no less than 9,518 bites by lice fed on trench fever cases did not sicken, nor did another who was bitten 13,224 times over a period of fifteen days. It was noted that while the younger patients with lice upon them always yielded to the desire to allay irritation by scratching, the older volunteers, in whom infection more frequently missed, were those who did not scratch. This observation led to the suggestion that infection might be due to the scratching in of the lice or of their excreta, and the successful result of the experiment of scarifying the skin and rubbing in crushed lice or the excreta of lice fed some time before on trench fever patients at once confirmed this view, the volunteers so treated developing the disease after an incubation period averaging eight days. The lice appear not to be infected immediately after feeding upon a patient with trench fever, but to become so after the lapse of a week, and in no case was infection carried by

excreta which had been passed within a few days after the feeding of the louse. These facts suggested to Major Ryan and his coadjutors that the parasite might complete its life-cycle within the body of the louse. That the louse is the carrier and that spontaneous infection cannot be considered, is proved by the fact that with the crushed bodies of normal lice, as with their excreta, no evidence of infection or its spread could be obtained. It is an important point to note with regard to prevention that in these experiments the infective louse excreta remained virulent for more than a fortnight when dried at the ordinary temperature of the room, and retained that virulence after exposure not only to direct sunlight but to a temperature of 56° C., whereas it is usually assumed that dry heat at this temperature suffices to prevent infection by lice. Lastly the conclusion curious, even if it has no pathological bearing, was arrived at that the louse cannot transmit infection to its own offspring. At the last meeting of the Society of Tropical Medicine, when Major Byam presented the report of his experiment Sir William Leishman stated that the conclusions reached by the work of the Trench Fever Committee in France were similar to those arrived at by Major Byam. One clear message of this work is that civilian populations run the risk of infection from soldiers discharged from the army or returning on leave, unless hygienic precautions are rigidly taken.

The Royal College of Surgeons in Ireland has conferred on Prof. Harvey Cushing, Harvard University, the honorary Fellowship of the Corporation, imitating thereby the action already taken by the Royal College of Surgeons of England. The Irish College is particularly chary of presenting anyone with their honorary diploma of the highest rank.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

FIGHTING TUBERCULOSIS—JIU-JITSU AGAIN—THE RED CROSS EVERYWHERE.

PARIS, May 14, 1918.

ONE more sanatorium to help meet the problem of tuberculosis in central France will be established as the result of a gift of 200,000 francs, just made by the Tuberculosis Bureau of the American Red Cross to the French Comité de Secours aux Blessés Militaires at Tours. This contribution, together with a fund raised by the local committee, makes possible the purchase of a large property known as "Bel Air," which the French society will convert into a large sanatorium for tuberculous civilians and réformés.

The Red Cross has already established tuberculosis hospitals of its own at Yerres and Plessis-Piquet, near Paris; at Lyons and elsewhere; has made a gift to St. Joseph's Hospital in Paris, which enabled it to remodel a building acquired by it for a tuberculosis sanatorium of 125 beds at a cost of 285,000 francs, and is constantly aiding tuberculosis hospitals in almost every department of France. In February alone it made grants of furniture, food, clothing, and medical supplies valued at nearly 100,000 francs to scores of hospitals outside Paris. Its grants of this kind from November through February total 575,000 francs and were made to 188 hospitals, with a total capacity of 15,385 beds. Its representatives are constantly in the field visiting tuberculosis hospitals and studying their needs.

Its diet kitchens erected in the yards of Paris hospitals serve more than 650 people a day. Since September, when it undertook the work of providing extra comforts—games, phonographs, colored bedspreads, books, and supplementary food rations—the total number of the voluntary exiles, many of whom entered the pavilion without hope of cure, merely to avoid the risk of spreading contagion, has increased 258 per cent.

One of the most interesting tuberculosis hospitals operated by the Red Cross is in the Hospital Sainte-Eugénie at Lyons, in a chateau presented to the city of Lyons by the Empress Eugénie and loaned by the city for the period of the war to the American Red Cross. This hospital is solely for tuberculous women repatriates sent back by the Germans as useless mouths. Until this hospital of 200 beds was opened there was very inadequate hospital provision for tuberculous women. Forlorn relics of undernourishment and depression, for the first time in three years they find at Lyons comfortable beds and adequate care.

Through the generosity of Mrs. Robert Woods Bliss two wagonloads of hospital equipment and supplies have been donated to the Bureau of Tuberculosis. The gift includes an *x*-ray machine, anesthetizer, autoclave, dental chair, etc., and the things are being distributed to the three hospitals operated by the Tuberculosis Bureau in and about Paris, the Edward L. Trudeau Sanatorium at Plessis-Robinson, the Chateau de la Fontaine Bude, Paris, and the Hospital Bénévole 19 bis, at 46, rue Docteur Blanche, Paris, and a certain amount of surgical equipment is being turned over to the general Red Cross supplies. This was part of the equipment at a hospital now discontinued.

When Lieutenant Desouches of the French Mission attached to the American Army, was in Paris last, he expressed surprise that Dr. McCurdy, head physical instructor of the Y. M. C. A. for the American Army, was not aware that jiu-jitsu was taught in both the French and British Armies. He said: "Go to the Ministère de la Guerre and see Commandant, or, as you say, 'Major,' Royet, directeur de l'infanterie. He is at the head of the physical instruction."

Commandant Royet received me courteously and at once spoke of jiu-jitsu in the French Army. "Why, we have had this going on for more than half a year, and all the men in the French Army have to learn jiu-jitsu, adapted to our requirements, and the feature is an enormous success. We encourage the men in every way to perfect themselves in what we call "corps-à-corps fighting," and this feature is of immense use. Before the war the method of combat was with the bayonet and was simply a system reduced to movements, manual exercises, and fencing. But since the war we have gone into the thing with entirely new motives. We have adopted real

hand-to-hand fighting, such as is imposed by the circumstances of this war. We require our men to kill their adversaries in this new corps-à-corps work. The bayonet is all right, but suppose you have no bayonet—which sometimes happens—well, a man can clutch his knife and attack his adversary. But suppose he has no knife, or, for some reason, cannot make use of it, at the psychological moment? What then? Why, he simply relies on his knowledge of jiu-jitsu. Jiu-jitsu is an art which takes time to learn thoroughly, but a soldier can learn enough in a month to give him complete confidence in himself when he has nothing but his hands, head, and feet to help him out, minus his gun, bayonet, grenade, or sword, as the case may be. What we teach enables our men to master their adversaries in almost all circumstances—even when the adversary is armed. He can disarm his adversary. You can see this in our schools. You simply kill a man with this jiu-jitsu properly applied.

"The one thing above all, in this jiu-jitsu work is that a soldier has complete confidence in himself. We have found it a splendid thing for the morale. When they advance at the front they are sure they can grapple with their adversary. Is not this a good thing to learn? The English Army has taken this up and it has found its value, and I can heartily recommend it to all the Allied Armies. The Minister of War is getting out a brochure containing this system of instruction and it will soon appear with illustrations and at the same time our Ministry will issue an English translation.

"Boxing is all right, so is the savate, or French substitute for boxing, so is wrestling, and so is also, of course, the Japanese jiu-jitsu. All come into our system of instruction. Let us take an example: Suppose a man boxes his adversary, knocks off his helmet. There is a fraction of a second of surprise. Then is the time to disarm him and finish him off with jiu-jitsu. Our system does not give jiu-jitsu the monopoly to the exclusion of all other means of getting rid of one's enemy, but it is an adaptation to our requirements. We use bayonet, knife, savate, boxing, and jiu-jitsu, all combined for practical purposes. When I say one month is sufficient for a man to learn our army physical development exercises, I do not mean any one at random; I mean a man who has had some physical development to start with. A man who never had physical development exercises cannot be expected to pick up jiu-jitsu in a short time. He takes longer to get the required skill. But he gets it. Believe me, our men are delivering the goods all right."

Recent air raids at Nancy have given the American Red Cross another chance to show its eagerness to make as bearable as possible the difficult living conditions of the women and children in the villages behind the army lines. The organization has just sent 2,000 francs to M. Mirman, Prefect at Nancy, for the emergency fund for victims of the last raid, in addition to providing twenty-two cases of clothing and several cases of foodstuffs to relief societies which were meeting the emergency. Members of the Red Cross staff at Nancy were the first to come to the rescue of the victims caught in the débris of a café on which a bomb had fallen.

The proprietress of this café lived in Belfort until 1914, when all the members of her family except two baby daughters lost their lives in an aerial bombardment. She made her way to Nancy and finally succeeded in getting a little capital together and starting this business to support the children. The bomb which struck this café killed the two little daughters and destroyed everything she had in the world, leaving her completely alone and penniless. The Red Cross is helping her make a third start.

Cooperation between M. Mirman and the American Red Cross in work for the harassed civilian population of Meurthe-et-Moselle has been carried on since last July, when almost the first work of the department of Civil Affairs was to help the French authorities in the direction of a refuge for 350 young children and mothers suddenly ordered out of the villages where there was continually danger of gas attacks. The refuge established in a former barracks near Toul is now sheltering about 500 children, too young to be trusted to wear gas-masks, and mothers of young babies, and the American Red Cross and the American Fund for French Wounded, acting together, have established in connection with the refuge a general dispensary, a children's hospital of 110 beds, of which 40 are reserved for maternity cases, and traveling dispensary service which carries American doctors and nurses to fourteen villages of Meurthe-et-Moselle. Some idea of the service which America is rendering to these unfortunate little French citizens can be obtained from the figures showing the work done in the month of February, when 189 children were treated in the hospital, 4,310 in the clinics, held in factories, schools, and town halls.

3. Chronic Myocarditis: A Clinical Study.—Henry A. Christian presents the results of a clinical study of 230 cases of chronic cardiac disease carried out in the wards of the Peter Bent Brigham Hospital in 1917. Of these 120 were positively diagnosed as chronic myocarditis and 5 questionably so, while 150 were regarded as cases of chronic valvular disease. The figures in 1916 were proportionately the same, being 156 of chronic myocarditis and 141 of chronic valvular disease; and in 1915 these cases were respectively 91 and 113 in number. The author summarizes the results of his observations as follows: There is a common chronic cardiac condition, in a general hospital for adults equal in frequency of occurrence to chronic valvular disease of the heart, which, for want of a better term, may be called chronic myocarditis. By this term is meant cardiac insufficiency from myocardial disturbance without organic lesion of the heart valves. A very large proportion (366 out of 407) of these patients on admission to the hospital are over forty years of age, and somewhat more are men than women. The heart is nearly always enlarged, and usually there is a cystolic murmur at the apex; but whatever its intensity or transmission, thickening or distortion of the valve flaps or chorda tendineæ is rarely found. Acute rheumatic fever and syphilis are both relatively uncommon in these cases, and neither plays any considerable part in the etiology. Chronic use of alcohol occurs in about one-third of the cases. High blood pressure is often found, but is absent in more than half of the cases. Chronic nephritis is often present, as is hypertension; but in seventeen out of forty-one cases at necropsy, the kidneys showed no chronic nephritis. Coronary sclerosis is an important factor in only about half of the cases. Increase of interstitial connective tissue is the lesion most found in the heart muscle, but in numerous cases the heart muscle seems practically normal except for hypertrophy of the fibers. Electrocardiography often gives evidence of disturbed muscle function. About half the cases show auricular fibrillation or flutter or the distortion of the ventricular complex, indicating some disturbance in the conduction system; but in even advanced cases the electrocardiogram often shows no significant disturbance. As to treatment, digitalis in the earlier breaks in compensation is a very efficient drug, and diuretics produce marked diuresis. He adds, however, that we have no certain knowledge of what really produces this type of cardiac insufficiency, and further study of these patients during life and after death is needed before we can have any adequate understanding of the mechanism and the causes of this condition.

7. A Case of Congenital Deformity of Hands and Feet. Barbara G. R. Crawford.

2. A Contribution to the Technique of Infected Wound Closure, More Especially Compound Fractures.—Captain Fraser B. Gurd believes that a more aggressive and direct method of treatment of infected compound fractures than is commonly employed in English hospitals is indicated. The techniques introduced by Rutherford Morison and Carrel, when properly employed, have each proved their usefulness in the hospitals in France. In a series of thirty characteristic cases, Captain Gurd has applied a modification of these methods with gratifying results. He describes in detail his method and divides the cases to be treated into: (1) Acute suppurative cellulitis with slough formation; (2) Open granulating wounds communicating freely with exposed bone and discharging purulent material in moderate quantities; (3) More or less quiescent bone inflammation communicating with the surface by means of one or more sinuses. In the first class of case, he employs substantially the technique suggested by Morison with the addition of the paraffin-gauze pack. In the second type of case, as soon as the infectious process has become localized an effort is made to approximate the tissues and skin edges and so mirimize the ultimate formation of new tissues with its accompanying sequelæ of adherent scars and nutritional disturbances. This is done by insertion of mattress sutures of heavy silk (No. 12-16) smeared with B. I. P. P. and protected by small rubber tubes or buttons. The wound is dressed with spirit or Dakin's solution. At each dressing, at six to twelve days' intervals, new sutures are inserted and the tissues gradually approximated. Invagination of scar is avoided by undercutting the skin. At each dressing the bone edges are carefully palpated with the B. I. P. P. pack brought in accurate contact with bare bones. Loose white bone fragments are removed and bone ends not covered with granulations within six weeks from time of injury are nibbled away. Once the bone is obscured by velvety granulations, the granulation tissue and as much as is deemed advisable of the scar tissue is excised and the wound tightly closed by means of superimposed layers of mattress sutures after B. I. P. P. has been carefully applied to the surface. In cases of the third type, the author advises excision *en masse* of as much scar tissue as possible. In the treatment of sinuses the value of passive hyperemia is emphasized and the danger of meddlesome packing with inert gauze. He points out that in the majority of these cases either bleeding has interfered with proper vision so that examination of bone is impossible or the wound edges are not easily approximated. In such cases he recommends that the exposed bone and soft tissues be mopped with alcohol and an excess of B. I. P. P. applied; paraffin gauze packs are pressed into position and the wound closed, as completely as may be, by means of protected mattress sutures. Such wounds are not dressed. In five or ten days the patient is anesthetized and sutures and packs removed. The wound surface is found clean, bright-red in color, and covered with granulations. There is no bleeding, examination is easy, and further interference readily carried out. The wound is again dried, "re-bipped," and closed by mattress sutures in layers. The author points out that, as Morison showed, frequent dressings of wounds, after closure, are unnecessary and harmful. Sutures should be left in position, if possible, for three weeks. The advantages of the method described are: Lessening of discomfort and pain to the patient, as a result of increase in interval between dressings and shortening of open wound period; improvement in functional result in consequence of less frequent disturbance of bone fragments during the dressing stage and earlier application of complete immobilization in cases in which this is indicated, a diminution in the number of adherent painful scars and nutritional disturbances, and earlier opportunity for secondary operations, such as nerve and tendon suture and massage, etc.; early transformation of patients from the "dressing" to "observation" class of men; shortening of hospital days per patient and consequent increase

in the usefulness of hospital beds; economy of dressing material, both by reason of the infrequency of dressings and shortening of the dressing period. Commenting on Captain Gurd's article, Colonel Sir Robert Jones points out the value of such a method as that described in that the rapid and successful closure of wounds, which otherwise might persist as sinuses for months, simplifies to some extent one of the greatest problems with which the army medical authorities are faced—the provision of hospital beds for the large numbers of wounded transferred to England.

5. A Note on Anaerobes in Soil Infected Wounds.—Captain Henry Goodale reports the conclusions reached in regard to anaerobes from evidence collected from a large number of cases in the Bacteriological Laboratory of Dartford War Hospital for Sir David Bruce's Tetanus Committee. He has found (1) That anaerobes or their spores persist in the deep tissues around bone and in scars after wounds have healed, or when they are covered with healthy granulations that give nothing but staphylococci on culture. (2) That anaerobes can find their way from an infected wound of the extremities to the serous cavities of the brain and pleura, and are found in these localities in connection with meningitis and pleurisy. (3) That anaerobes are found in metastatic abscesses of the lung resembling in type the organisms found in the soil-infected wound of the patient, and the symptoms of these patients are those of general septicæmia. He states that he has not entered into any speculations as to the precise way by which anaerobes find their way from one part of the body to another; it appears certain that they produce a substance that paralyzes the polymorphonuclear leucocytes and inhibits phagocytosis, this being one of the factors which accounts for the rapid progress of acute bacillary gangrene. Nor has he spoken of symbiosis, which is another important factor in dealing with anaerobes. He hopes, however, that in view of the importance of the subject the few observations he has made may be of some value.

5. A Case of Cerebral Toxemia—? "Botulism." James Law Brownlie.

3. The Part Played by Concomitant Infection With Anaerobic Organisms (Other than B. Tetani) in the Causation of Tetanus.—Captain William J. Tulloch points out that (1) There is good ground for believing that the ancillary part played by *B. welchii* in the causation of tetanus is clearly defined. The capacity of this organism for doing harm in the connexion under consideration can be almost eliminated by the use of the antitoxin for *B. welchii*. (2) The capacity shown by the toxin of *Vibrion septique* for stimulating the growth of tetanus spores *in vivo* is more variable than is that of *B. welchii*. Experiment VII indicates, however, that it too may play a part in the causation of tetanus. (3) It follows from conclusions 1 and 2 that antibodies to the toxins of *B. tetani*, *B. welchii*, and *Vibrion septique* should be included in all serum employed for the prophylaxis of tetanus. (4) While such a polyvalent serum promises to reduce still further the incidence of tetanus it would be too optimistic to assume that it would absolutely eliminate that disease, for infections other than those dealt with in this communication may also play a part in stimulating the growth of *B. tetani* in wounds. One of these, *B. oedematiens*, the writer proposes to investigate immediately.

The Disturbances of the Internal Secretions in Eunuchoids.—E. Voelckel gives a general survey of the question of testicular insufficiency and then gives the case history of a male aet. forty years, with hypoplastic testes. His secondary sexual characteristics were insufficient; in height he was below the average in relation to body weight, while lymphocytosis was insufficient. Voelckel was unable to find any change in the sympathetic or autonomous excitability. Likewise, he was able to note that the conditions of metabolism were normal by the following tests: (1) A mixed diet, at the rate of 3000 calories by weight, maintained the subject at his normal weight. A diet of 1800 calories resulted in a loss of weight, rapidly compensated by a return to the diet of 3000 calories. There was, consequently, no disturbance in oxydation. (2) There was no alimentary glycosuria nor hyduria. This subject can, therefore, demonstrate either theory concerning the relationship of the endocrine glands between themselves.

Is There a Disease of Aviators?—W. Hirschlaff comes to the conclusion that there is no clinical picture belonging properly to aviators. The phenomena that they may offer is quite as well met with in the case of mountain sickness. The writer mentions, among others, the following phenomena: pain in the ears in rapid changes of altitude, particularly in the descent. The aviator automatically deals with them by making movements of deglutition or yawning (the presence of a tubotympanic or sinunasal obstruction may cause violent pain in the blocked-off cavity). The want of oxygenation does not usually give rise to any trouble, as the aviator is provided with a tank of oxygen. The blood pressure is usually increased by about 20 mm. Hg. at the end of the flight, as compared with the initial pressure. Likewise, the pulse rate increases from 20 to 30 per minute. Organic cardiac disturbances are unusual. The most frequent, and at the same time the most serious disturbances, are of a nervous nature: restlessness, insomnia, functional cardiac disturbances. Aviators easily become the prey of neurasthenia, while on the other hand, psychopathic disturbances (for example, traumatic neuroses) are rarely encountered among them, this fact being explained by the selection of the men taken into the air service.

The Diagnosis of Fluid Collections in the Knee Joint.—Pels-Leusden has come to the conclusion that the present methods of diagnosis which, as far as he is concerned, are limited to the patellar shock, are wanting in "finesse" and are insufficient, and in this we agree. This procedure, which, according to Pels-Leusden, is the only one resorted to (in his country), but can very well be completed by a method more apt for detecting small fluid collections in the knee. This consists in placing the leg in complete passive extension, and in this position the hands of the examiner being placed one above the other below the knee joint, can produce fluctuation of the fluid contents on either side of the patella.

The Cure of Cutaneous Ulcers and Bone Fistulæ Following Wounds from Missiles, by Immunized Skin Flaps.—M. Katzenstein has noted that grafts of healthy skin often die in their struggle with the infected wound which they covered. Katzenstein proposes to overcome this difficulty by immunizing the flaps, and to attain this end he treats the skin which shall serve as a graft

by the application of the dressings coming from the wound. An inflammatory process ensues which renders the skin more apt to grow over the grafted area. This procedure has been utilized in cases of cutaneous ulcers treated in the first place by Thiersch's grafts, a fixation of the epidermic bits occurs in spite of the local suppuration; the pus can be given exit through the graft, or may even be eliminated spontaneously. The pedunculated flaps destined for closing the musculocutaneous ulcers or bone fistulæ will likewise hold much more readily if they are first treated by the septic products of these ulcerative processes. The writer insists on the fact that numerous wounded men who had undergone long and varied hospital treatments rapidly recovered after the application of the method advised.

Sealed Dressings.—F. Härtel, taking into consideration Bier's researches on the conditions of tissue regeneration, criticises the absorbing dressings which are almost universally employed. These viciate the conditions of existence of the deeper tissues which habitually live in a fluid medium. The absorption by aspiration of the gauze dressings interferes with the development of the granulations, without mentioning the inconveniences attendant upon change of dressings (pain, tearing of the wound tissues, etc.). In certain conditions, pus is a useful adjuvant to the process of cicatrization. The technique employed by Härtel consists in the use of impermeable material which covers the wounded surface completely. The surrounding skin is covered with a dermatol-zinc oxide ointment, after which the impermeable dressings are held in place by gauze, and the whole retained by a roller bandage. If retention of fluids is too great, drainage of the declivitous parts of the wound cavity may be resorted to. The result of this method is, that after a few days under the free production of pus will be found granulations in full development. This procedure is to be used in all cases of clean, open wounds, but in irregular, doubtful wounds it is contraindicated.

The Presence of Virulent Tubercle Bacilli in the Blood After the Exhibition of Tuberculin, in Cutaneous and Other Tuberculoses.—W. Schönfeld finds that the passage of bacilli into the circulation in cutaneous tuberculosis is infrequent. The production of this bacillemia was not made evident by injections of tuberculin or the intravenous use of cyanide of gold. Finally, Schönfeld considers as doubtful the attribution of an atypical tuberculous reaction to a tuberculosis in the given subject. These conclusions have been come to from results derived from a series of injections made in the guinea-pig of blood taken from patients before and after treatment with tuberculin.

The Cause of Essential Night-Blindness.—L. Koeppe again brings up the question of hemeralopia on account of its present importance in military medicine. In opposition to those who attribute this visual defect to lesions of the nervous system, retinal malformations, circulatory disturbances, etc., the writer places the cause in a diminished transparency of the cornea and lens. Evening light produces cecity, because the relative opacity of these structures intercepts the light rays, so that the point of retinal excitation is not reached. Koeppe has been able to demonstrate these anomalies in transparence by means of a Nernst lamp provided with a slit thus giving a centuple enlargement. Hemerolopic patients frequently offer these changes, while by an ordinary visual examination no change of the cornea or lens will be detected. The writer believes that his method is a means of verifying hemerolopia in subjects who claim to have night-blindness and that any simulation on the part of the subject can be detected.

Frequent Diagnostic Mistakes, Particularly in Physical Diagnosis.—A. Heinecke, who is the director of an observation clinic to which all doubtful cases or those in which the diagnosis is difficult are sent, as well as soldiers requiring expert opinion as to their military aptitude, offers this paper. He has been able to send back to active service 77.6 per cent. of the cases submitted to his examination, 47.9 per cent. returning to the front. He has been able to note that the most general diagnostic error has been that of pulmonary tuberculosis which did not exist. He has become very critical in regard to the physical diagnostic means generally employed. Thus, of all findings by auscultation, he looks upon râles as the only certain sign (when all characteristic evidences of pulmonary tuberculosis are absent) of tuberculosis. Comparative percussion of the apices may cause erroneous interpretation when there exists a slight scoliosis, even when the spinous apophyses are perfectly in line. Asymetry of the claviculæ and ribs is also a source of error in physical diagnosis. To conclude, the writer opposes the modern tendency to make a too fine physical examination as this only tends to increase the number of mistaken diagnoses.

March 2, 1918.

Epidemic of Diphtheria in Basle.—Massini refers to an epidemic which prevailed during the late winter. A number of the victims were treated by the author in the Civil Hospital. The incidence was rather cumulative than epidemic, and in the last month five of the interned children died from laryngeal diphtheria. There were no deaths from the pharyngeal and nasal localizations. All the recovered children received their serum either early (pharyngeal cases 2.5 days) or late (nasal cases 20 days). The dead children did not receive serum until an average of more than 6 days had expired; while in children who recovered from laryngeal diphtheria the interval was but 2.3 days. It is very rare for death to occur in diphtheria when the membrane has been expelled in the first two or three days, and this result we see when serum is given early. Serum sickness in the form of a rash was seen 12 times, while anaphylactic phenomena were quite absent. The author would not term this epidemic a severe one, for the measure of severity is high morbidity and mortality in adults. It is, of course, conceivable that in such cases virulence can attain such a pitch that the action of serum becomes problematical.

Is Salvarsan of Value in Amebic Dysentery?—Heim asks if salvarsan may not be the equal of emetine as an antiprotozoan remedy. A study of recent literature shows that this practical subject seems to have received little attention. The author having treated a patient, without success, with emetine, obtained his chance to test arsenobenzol. The case was eminently amebic in clinical characters, relapses occurring from time to time over a period of years. The Wassermann was negative, so that no claim could be urged of a syphilitic substratum. Amebus were present in the stools in small numbers only. The patient, whose relapse had at first been mild and controllable with emetine, had become much worse, and was confined to his bed with many daily evacuations. The author chose to use neosalvarsan in the form of an enema, and benefit was at once apparent. After six of these enemas during a fortnight the patient was practically well. He had a mild relapse six months later which yielded to a single enema of neosalvarsan. Similar results were obtained in other cases, so that the author does not hesitate to use salvarsan whenever emetine proves unequal to the task of controlling the disease.

Night Blindness in Troops.—Landott has separated these into three classes. In false hemeralopia or nocturnal amblyopia we have to deal with refractive errors including lesions of the cornea. In true hemeralopia we have to deal with retinochoroiditis, retinitis pigmentosa, choroiditis, etc., the effects of which on visual acuteness had been latent before the night life of the war. The first class may require only glasses, while the second should be transferred to the auxiliary services. Finally we have the hemeralopia due to poor food and malhygiene which yields rapidly to regimen.—*La Presse Médicale.*

Book Reviews.

Blood Transfusion, Hemorrhage and the Anemias. By Bertram N. Bernheim, A.B., M.D., F.A.C.G., Instructor in Clinical Surgery, the Johns Hopkins University; Captain, Medical Officers' Reserve Corps, U. S. Army; Author of "Surgery of the Vascular System," etc. Price, $4.00. Philadelphia and London: J. B. Lippincott Company.

Bernheim has rendered a genuine service to the profession in writing this book at the present time. The work is the logical outcome of the author's large practical experience in blood transfusion during the past few years; in fact, since the procedure became recognized as an invaluable adjunct to the therapeutic armamentarium in the treatment of the anemias. He begins with an introductory note containing an interesting historical résumé of transfusion from the earliest times down to the present. Four periods are demarcated. The first comprises the early abortive attempts of archaic interest only. The second is the period initiated by Carrel's work on blood vessels, which was the beginning of modern research into the problem. This period includes Crile's arteriovenous direct transfusion technique. The third period is that of indirect transfusion of whole blood by means of the syringe-cannula technique, introduced by Lindeman, and which is in reality a revival of von Ziemssen's old method long forgotten. The fourth period is just beginning, according to the author, and may well be termed the Period of Anticoagulants. The book contains twelve chapters with the following captions: Blood and the phenomenon of bleeding; diagnosis of hemorrhage; control of hemorrhage, factors involved in a determination of danger limits, blood pressure; indications for transfusion; dangers of transfusion, hemolysis and agglutination; selection of donor for transfusion, dangers to donor, treatment of donor after transfusion; methods of transfusion, technique; transfusion for acute hemorrhage and shock, etc., etc.; transfusion for anemic and debilitated conditions in general; primary pernicious anemia; transfusion for hemophilia, melena neonatorum, purpura, jaundice; leucemia, splenic anemia, certain toxemias. Each subject is treated in a thorough manner without dwelling upon irrelevant details. The indications for transfusion are considered at length and numerous clinical citations are included to emphasize its value. A list of references is given at the end of each chapter, pertaining to the topic under discussion. The book is concluded by an appendix containing hemolysis and agglutination tests to be carried out before transfusion. To anyone interested in the subject of blood transfusion, Bernheim's work will appeal as being a sound, practical treatise well worth perusal.

The Medical Clinics of North America. New York Number. November, 1917. Vol. 1, No. 3. Published Bi-monthly. Price, $10.00 per year. Philadelphia and London: W. B. Saunders Company.

This number of the Medical Clinics is replete with much valuable and up-to-the-minute information on a well selected list of subjects. A few of the more important ones might be mentioned as illustrating the general high level of the contents. Dr. Warfield T. Longcope, in his clinic at the Presbyterian Hospital, adds a case of Vaquez's Disease to the literature of this rather rare malady. Prof. Graham Lusk gives a very practical dissertation on "Calories in Common Life," being an estimate of food requirements in health and disease. Dr. Warren Coleman has a contribution on typhoid diet with an exposition of the high calory principle, rules for calculation of such a regimen, ménus for the different stages of the infection, cautions to be observed, and the question of hemorrhage in its relation to diet. The writer states that he believes the principle underlying the high calory diet is applicable to other febrile diseases than typhoid fever. Dr. Rufus Cole contributes an excellent article on the treatment of lobar pneumonia, in which the importance of identifying the type of infecting organism is emphasized. Detailed directions are given by Cole regarding the use of antipneumonic serum. Dr. Alfred E. Cohn on the clinical pharmacology of digitalis gives many useful suggestions as to the use of this all-important drug. The newer ideas on protein sensitization in the human is considered by Dr. Robert A. Cooke in two lectures, during the course of which he takes up the diagnosis of bronchial asthma and hay fever, and discusses the value of protein injections in these conditions. The value of the fluoroscopic method of diagnosis in digestive diseases by Dr. Arthur L. Holland, and a symposium on diabetes by Dr. H. R. Geyelin are two contributions of decided merit.

Vagotonia. A Clinical Study in Vegetative Neurology. By Dr. Hans Eppinger and Dr. Leo Hess of Vienna. Authorized translation by Drs. Walter Max Kraus, A.M., M.D., and Smith Ely Jelliffe, M.D., Ph.D. (Second, revised and corrected edition.) Nervous and Mental Disease Monograph Series, No. 20. Price, $1.00 net. New York: The Nervous and Mental Disease Pub. Co., 1917.

Just as the broad term "epilepsy" is coming to be applied to a smaller and smaller group of patients, so increasing knowledge of the obscure regions of neuropathology will decrease the ranks of patients whom we have been in the habit of labelling simply "nervous." The autonomic nervous system is probably the least understood of any part of the human body, and the existence of a disease syndrome consisting of abnormal irritability of this system is little enough appreciated by the large majority of the profession to make the present volume very welcome. The first edition was rapidly exhausted, and this one is practically a reprint, although some minor changes have been made. It is a remarkably clear presentation of the known facts of the subject, with suggestions for future research, the whole bound in the Continental method—that is, heavy paper covers, a custom at which many American doctors are wont to carp.

A Treatise on Regional Surgery by Various Authors. Edited by John Fairbairn Binnie, A. M., C.M., F.A.C.S., Kansas City, Mo. Vol. III. Octavo of 830 Pages with 521 Illustrations. Price $7.00 net. Philadelphia: P. Blakiston's Son & Company, 1917.

This is the final volume of this set and while, according to the announcement opposite the title page, it is supposed to cover only the surgery of the extremities, there is also a section on thoracic surgery which should have appeared in the first volume along with the articles covering the surgery of the heart, pericardium, diaphragm, and breast. Lilienthal and Gerster's section on thoracic surgery, although hidden away at the back of the book, is not only one of the most important, but one of the most scholarly in the volume.

The standard set by the articles in the second volume perhaps led us to expect too much of this one, and possibly that is one reason why this seems somewhat disappointing. In this volume particularly there is entirely too much overlapping of material. There seems to be no good reason why such subjects as traumata (exclusive of fractures and dislocations, which require individual consideration), osteomyelitis, tumors, and numerous other subjects could not have been covered by one author, who might point out any occasional differences arising when one or the other extremity was concerned, rather than for one author to describe, for example, boils, carbuncles, bone cysts, etc., etc., as affecting the upper extremity and then for another author to duplicate the process for the lower extremity. A great deal of space could have been saved without loss of anything essential.

The following authors have contributed to this volume: Drs. James F. Mitchell, J. W. Perkins, A. F. Jonas, Dean Lewis, E. H. Bradford, Robert Soutter, J. F. Binnie, W. J. Frick, Charles Herbert Fagge, Emmet Rixford, Stanley Stillman, David McCrae Aitken, Howard Lilienthal, John C. A. Gerster, Sir W. Arbuthnot Lane and Sir Robert Jones. Among the sections that deserve special mention are those on fractures and dislocations, both of the upper and lower extremities, by Perkins, Jonas, Lane, and Fagge; the long section on diseases of the upper extremity by Dean Lewis; the sections on deformities of the lower limbs, congenital dislocation of the hip, and infantile paralysis by Jones and Aitken, and the section on thoracic surgery by Lilienthal and Gerster.

(*Continued from Vol. 93, page 1149.*)

Neurocirculatory Asthenia.—DRS. WILLIAM H. ROBEY, JR., of Boston and ERNST BOAS of New York presented this communication, which was read by Dr. ROBEY, and in which they said that the condition to which the name "neurocirculatory asthenia" had been recently given had been previously described under the names of "soldier's heart" and "effort syndrome." The symptoms of this condition were breathlessness on exertion, tachycardia, palpitation, precordial pain, vertigo, fatigue on slight exertion, lassitude, high blood pressure, and general nervous instability. All the symptoms were exaggerated by a slight amount of exercise. The condition was known in civil practice, but because the individuals suffering from it spared themselves and took up certain work compatible with the condition it was not so frequently observed by the civil physician; but in the Army, where everyone must do the same work and must adapt himself to the work, it was quite frequently observed and was responsible for a certain degree of invalidism. The condition was often diagnosed as organic heart disease, because of the precordial pain usually present and the elicited thrills which suggested mitral stenosis. The thrills, however, in the condition described, were systolic in time. In some soldiers the condition was present before entering the service, in others it occurred after entering the service, and in still others only the greatest stress gave rise to that condition. Until recently there had been no category of light work in the army and the men presenting the symptoms described had been usually discharged. Lewis treated these cases with calisthenic exercises, progressing slowly from one form of exercise to another, and those that could not go through with the entire series were discharged. In the essayist's experience that form of treatment had no value as a cure, but was of some diagnostic value. They had become convinced that the condition was due to an inherent nervous instability. A vast number of the patients gave a family history of nervous disease and their personal histories indicated that they had always been somewhat unstable; they could not stand any extra strain and could not meet conditions requiring special effort; many gave a history of enuresis in childhood, objectively they showed twitching of the fingers and emotional instability, and were subject to crying. Some writers mentioned hyperthyroidism in connection with that syndrome, but the authors had not observed any changes in the thyroid.

Sir JAMES MCKENZIE of England, who was introduced by the Chairman as the man who had made the study of cardiovascular disease popular here and abroad, said he wished to preach the gospel of clinical investigation. Instead of spending so much time in studying what happened when the patient was dead, the time should be devoted to the study of the patient's symptoms. The sensations of the patient should be studied accurately. Such symptoms as fever and pain had not been studied sufficiently. Pain was often described as diffuse. In his opinion, however, there was no diffuse pain, but it was governed by definite laws. During the Civil War he had read descriptions of "soldier's heart," but when he had visited the hospitals nobody was able to demonstrate that condition to him. In England he had grouped 500 soldiers who were discharged from the service because of valvular disease of the heart and disordered action of the heart, and in 90 per cent. of the cases there was no organic disease. The murmurs which had been elicited were functional or, better, physiological. When a murmur was found the question should be, What deficiency did the murmur produce? The entire problem was that of the myocardium and not murmurs. He had followed a case with a presystolic murmur for eighteen years and then the murmur had disappeared. He had never been able to hear a Flint murmur nor a Steel murmur. He did not object to the name of effort syndrome or the new name neurocirculatory asthenia, but the trouble was that many stopped at names, as soon as a condition was labeled that seemed to solve the problem. The symptoms should be more carefully studied. The asthenia was not confined to the nervous system, but the entire system was asthenic. In many cases of functional heart condition, by careful questioning of the patient, one frequently elicited a history of cough, diarrhea, malaria, etc., a week or ten days previously, and these patients were simply convalescing from some form of an infection. He had sent a man with an aortic murmur into the trenches with a certificate that he was able to do easy work, and whenever that soldier wanted a rest or a little vacation he would go to the division surgeon and the latter, upon listening to his heart, would shake his head and immediately send him to the hospital. Any man when subjected to strong physical exertion gave way somewhere—some got tired in their legs while others got short of breath. The symptoms of exhaustion, in his opinion, deserved very careful study. He did not suggest the particular exercise Dr. Lewis was using in the heart conditions mentioned; all he wanted was that the patients should do something in which they were interested. Any man who was able to take exercise and enjoy it was doing his heart good and not harm.

Dr. WARFIELD of Milwaukee said he was very much interested in this subject. He had been in Camp Jackson, where 50,000 men passed. He had seen all the heart cases and he wished to know how the condition described could be determined. The exercises given were in many cases sufficient only to bring out the gross lesions; many patients could perform various exercises, return to normal easily, and still have a murmur. He thought such men should be retained in the service. He wished to know if there was a way whereby in the recruiting station it could be told who was going to break down. He had only seen one case that he was able to diagnose as "effort syndrome." Some were cases of hyperthyroidism, some cases were called by the psychiatrist psychoneurosis, and some turned out to be tuberculosis, but there were many cases with trivial heart lesions. The question was an important one for those who were doing recruiting duty.

Dr. LITCHFIELD of Pittsburgh wanted Sir James MacKenzie to say something about the influence of tobacco on the heart. With the outbreak of the war the tobacco trust, through adroit advertising, had impressed the public with the importance that tobacco played in keeping the soldier in good spirits, and as a result everybody—from friend, relative, to various charitable organization—had made a special effort to see that the soldier was well supplied with tobacco. The excessive supply of which the soldier found himself to be the possessor resulted in its excessive use, in consequence of which various functional heart conditions had developed. When the smoking was stopped, as upon admission to a hospital, the condition quickly disappeared.

Sir JAMES MACKENZIE said that at the beginning of recruiting in England many young men were shocked to know that they had murmurs; many had consulted him because they had been turned down by the recruiting officer. He wished to impress upon the hearers that perfectly physiological hearts might have murmurs and a murmur systolic in time might be perfectly normal. If there was no enlargement of the heart, if the rhythm and rapidity were normal, and there was good response to effort, one should forget about the murmur. In his opinion there was no such thing as mitral regurgitation of first or second degrees; he had kept records of the rejected cases and had become convinced of the harmlessness of murmurs. One man who had had a rough systolic murmur at the apex had been rejected by the army six times, but upon Dr. MacKenzie's personal recommendation had been finally accepted and, after three years' hardest work in the trenches, was as vigorous as ever. Hyperthyroidism was another craze. He had examined three hundred cases that were diagnosed so and in none was he able to find an enlarged thyroid. Tobacco in many cases might be a predisposing cause, but was only one symptom and one should

never depend on one symptom alone. In his book he had described an X type. He called it X because he did not know what the condition was due to. Patients suffering with that type of heart condition were poorly nourished, their peripheral circulation was poor, they did not respond to cold, were afraid of a cold bath, were red-nosed, and of an irritable temper. Such people had irritable hearts and under army life would easily break down. Some would call them psychasthenia, but it was more probable that the condition was due to an ileostasis or some other gastrointestinal condition.

Dr. Oppenheimer of New York said that last summer the Surgeon-General had sent six American officers of the Reserve Medical Corps to the British Military Heart Hospital, with which Sir James MacKenzie had been connected since its inception. After serving there for several months they had written an independent report in which they suggested the new name, neurocirculatory asthenia, for the now familiar symptom complex. After the completion of the report Dr. Thomas Lewis had written a brief but valuable foreword showing its military bearing in relation to the young American forces. By some mistake, however, the paper was printed in the April issue of *The Military Surgeon*, with Dr. Lewis as the author; the names of the six American officers really responsible for the report and also for the introduction of the name were entirely omitted. This explanation he thought might make certain parts of that paper more intelligent. Several other names had been used, such as "disordered action of the heart," "irritable heart of soldiers," "effort syndrome," "athletes' heart," "cardiac neurosis," etc., but the use of any term which directed the soldier's attention to his heart handicapped him and the officer who dealt with him. Neurocirculatory asthenia overcame that objection; moreover, the name was not meant to imply any theory of the fundamental pathology, which was still unknown. It was purely a descriptive term, indicating that in this syndrome there were nervous and circulatory symptoms associated with an increased susceptibility to fatigue. Since returning to America there had been an opportunity to compare the cases among the American recruits who had broken down in training with such symptom with the British soldiers who were invalided from the front with "D. A. H." The condition as seen in England and America was identical, but the cases here were milder and, as Major Robey and Captain Boas pointed out, belonged almost entirely to the constitutional group; *i.e.* to the group that had symptoms prior to entrance into service. The question of fundamental pathology, especially that of hyperthyroidism, was here complicated by the great prevalence of thyroid enlargement in the "thyroid belt" of the Great Lakes. Some of these men had a simple thyroid enlargement, some suffered from thyreotoxic hearts, but it was exceptional to find a typical case of Graves' disease. As to the question of nervous instability which Major Robey had emphasized, Captain Rothschild and the speaker had taken in detail the family and the personal histories of one hundred soldiers in Colchester, and found that 46 per cent. had predisposing neuropsychic factors in their family and previous histories, but that thirty-nine had absolutely negative histories and had given valuable military service before breaking down. Dr. Warfield had asked a very important question. In answer, one might say that only a certain percentage of cases could be picked out in the initial examination of drafted men, for the disorder might not develop until the soldier was exposed to the conditions of modern warfare. In view of the abundance of perfectly normal recruits in this country, every man who was sent overseas should be fit, and, for the present at least, it was sound to reject doubtful or borderline cases.

Dr. Jacobi of New York said in addition to the mitral murmur the presence of hypertrophy or dilatation, or both, was also necessary in order to make a diagnosis of organic heart disease. Some murmurs were changeable, they were present one day and not the other; some appeared only after exertion. Many conditions called myocarditis were due to nervous irritability as a result of excessive use of tobacco. In some patients murmurs appeared after running up and down stairs, but disappeared after ten minutes' rest. Such people could very easily do a certain amount of good work and need not be rejected from the service.

Dr. Robey, in closing the discussion, said that out of 26,000 men examined only a few cases of organic disease had been found; the entire question was that of muscular efficiency. Out of the 26,900 men examined only 200 were diagnosed as subjects of circulatory asthenia, and as they had not been pressed for men and it was a real condition, it was thought best to reject them. There was no way of telling at the recruiting station who would break down as a result of such a condition.

Newer Aspects of Digitalis Therapy.—Drs. Joseph H. Pratt and Hyman Morrison of Boston presented this communication, which was read by Dr. Pratt. They stated that the usefulness of digitalis was not appreciated until recent times, although in 1785 Withering called attention to its therapy in a very exhaustive paper called "The Truth About Fox Glove." His thesis was to continue administration until the drug acted on the heart, kidney, pulse, or stomach and MacKenzie a hundred years later recorded the same postulates. The essayists stated that most of the digitalis on the market was of poor quality and variable in strength, of thirty samples tested, twenty-four of which were native grown, seventeen were below U. S. P. strength and the extreme of variation was 700 per cent. Physicians feared unjustifiably large doses of this drug; weak preparations were given and the use of the infusion should be condemned. One c.c. of a good tincture of digitalis produced a physiological effect in three days. Regarding strophanthin they considered the drug intravenously a life-saving measure. Unpleasant results which followed its administration were due to large doses; they never gave more than one-half milligram per dose. They were convinced that in some cases strophanthin produced therapeutic effects which could never be obtained by digitalis. They emphasized the importance of using an active preparation and in sufficiently large doses to obtain results.

Sir James MacKenzie said he could give support to everything Dr. Pratt had stated; he, however, never found a weak preparation in England. It grieved him in years bygone to see medical men from the United States pass through England jump over to Germany and come back with some kind of an instrument, carrying it as a false-god. They might have waited a little to see what England was doing. Undue importance was given to laboratory investigation and the clinical side was neglected. In England they had followed more the system of clinical investigation and men like Hunter and others who were known in this country as surgeons were primarily clinicians. Withering, under the system of clinical observation, had been able to write a better paper one hundred and twenty years ago than anyone had written since with all the laboratory methods at hand.

Second Day—Friday, June 14.

Symposium on Pneumonia: Unique Findings Gathered from the Observation of Eleven Hundred Cases of Pneumonia in a Base Hospital.—Dr. Arthur A. Small of Chicago presented this paper. The cases studied comprised 857 lobar and 208 bronchial pneumonias. The ordinary lobar type, as seen in civil practice, prevailed during September and October, but in November and December the incidence became greater with proportionately more bronchial cases and a higher mortality. Thus in the last two named months the mortality was 29 per cent. and this continued during January, and during that month the mortality of the bronchial cases rose to 53 per cent. This high mortality was difficult to account for unless it was attributed to the fact that many of the cases were secondary to measles. A surprising feature of the so-called streptococcic bronchial pneumonia cases was the paucity of symptoms both subjective and objective. A slight cough, a few rales, and perhaps no subjective complaint often formed the entire clinical picture at first, twelve to twenty four hours later there would be a small consolidated area with tubular breathing, usually in the scapular region. A malignant type sometimes occurred, the patient would be slightly ill in the morning, admitted to the hospital in the evening, and a fatal result would occur the following morning. Post-mortem findings would reveal lymphadenitis, acute pleuritis, bronchial and lobar pneumonia in the same patient. Empyema had occurred in 9.25 per cent. of

all cases. The condition was very hard to diagnose. *X*-ray pictures revealed pocket formation of pus in locations that could not be detected by exploratory puncture or from physical signs. Forty-eight per cent. of the empyemas were due to streptococci. Many cases were diagnosed as meningitis on account of the presence of Koenig's sign, stiffness of the neck, and headache. Others presented symptoms of appendicitis. Jaundice was not infrequent especially in the negro; another frequent complication was pericarditis. The high mortality might be attributed to the fact that during the first four months the physical condition of the men was poor, there was a great deal of dust in the camps, the men frequently went to bed with wet clothes on, the prevalence of measles. Tonsils were enlarged in many cases, which in turn predisposed the men to many respiratory infections as coryza, bronchitis, etc., which in turn contributed to the development of pneumonia.

An Epidemic of Streptococcus Pneumonia and Empyema at Camp Dodge.—Drs. JOSEPH L. MILLER and FRANK B. LUSK of Chicago presented this communication which was read by Dr. Miller. They stated that they had observed 740 cases of pneumonia of both types in Camp Dodge between the months of September and April. Between the months of September and March the pneumonias were mostly of the pneumococcic type with the same mortality as observed in civil life, but along the month of March the streptococcic type developed. This type of pneumonia gave an unusual high mortality and in a large per cent. of cases developed empyema in which the mortality had reached about 60 per cent. The colored troops, however, were less liable to empyema but the mortality from uncomplicated pneumonia was higher in the colored than in the white. The patients appeared very ill. Marked toxemia was present but physical signs were less definite. The rapidity of the occurrence of empyema was remarkable, frequently following within twenty four hours after patient's admission to the hospital. The greatest difficulty was encountered in the detection of fluid. Physical signs would show good breath sounds, bronchial breathing with some rales, the patient frequently dying twenty-four hours later and presenting upon autopsy large amounts of fluid which was due to the peculiar pocket formation, rendering it almost impossible of detection by means of physical signs and even by exploratory puncture. The *x*-ray was resorted to frequently, every case admitted to the ward was *x*-rayed within the first twenty-four hours and every five days while the temperature continued to show any elevation. Many cases of bronchitis with a temperature of 101°, under *x*-ray examination proved to be pneumonia; but while the *x*-ray was of value in detecting consolidation it was of far less value for the detection of fluid, and frequent aspiration had to be depended upon in order to make a diagnosis of fluid. Empyema developed in 33 per cent. of the pneumonia cases and many empyemas were complicated by peritonitis, suppurative pericarditis, and arthritis. While the mortality from non-complicating pneumonia was higher in the negro than in the white, the mortality from empyema in the negro was lower than in the white. The contributing causes of the epidemic were the dry, warm, and exceedingly dusty month of March, the frequent drills, the prevalence of coryza and bronchitis, overcrowded condition of the sleeping rooms, cots being too near one another, and the fact that the windows were not kept open, which was especially true of the colored troops who in addition to closing the windows frequently covered up their heads with their blankets. The treatment during the epidemic consisted in the administration of 1 c.c. of a carefully standardized tincture of digitalis every three hours until the crisis occurred, the administration of morphine for cough or restlessness and the administration of camphorated oil in bad heart cases. The streptococcic empyemas did not respond well to early surgical interference; the first thirty-two cases were operated upon early with quite disastrous results. Repeated aspirations until the fluid became purulent when operation was resorted to was the plan later on adopted and better results were obtained. The improvement in the results, however, was only apparent, as of the thirty-two cases operated on early 56 per cent. resulted fatally, and of eighty-one cases with later operations 51 per cent. were fatal. The patients operated on early, however, died much sooner than the cases of later operations. The death in many cases was due to the intense toxemia and not empyema. When localized pockets of pus remained undiscovered the patients died eventually. Whenever the pus was localized in one pocket he got well no matter what manner of treatment was followed.

A Clinical Study of Eight Hundred Cases of Pneumonia.—Drs. WILLARD J. STONE of Toledo, Oh.o; BRUCE G. PHILLIPS and WALTER P. BLISS of New York presented this communication, which was read by Dr. Stone. The study embraced all cases of pneumonia treated during the period of eight months, of which approximately 650 were primary lobar pneumonia and 150 pneumonias following measles. The infection had been of a severe type. In only a small number of cases was the Pneumococcus Type I present. In a far larger number of cases the *Streptococcus hemolyticus* prevailed. The occurrence of empyema was unusually frequent and the mortality as a result of that complication was high. The pneumonias following measles were of both the lobar and bronchopneumonic type. Empyema occurred in twenty-one per cent. of all cases. The mortality of empyema due to the pneumococcus was 25.8 per cent., while that due to the streptococcus mortality was 74.2 per cent. Early operations for empyema resulted in a high mortality which had been reduced by preliminary aspirations and intrapleural lavage until the pneumonic process had subsided when operation followed.

Streptococcus Pneumonia.—Dr. JAMES G. CUMMINGS of Ann Arbor, Mich., read this paper. He stated that during the winter months at Fort Sam Houston they had a large number of cases of pneumonia which was of a severe type complicated very frequently with empyema. The investigation showed *Streptococcus hemolyticus* was the cause of the epidemic. The germ was isolated from the throat sputum and from pleural fluids. The germ was frequently spread through the use of milk into which it had gotten from the udder of the cows infected by humans. This organism was frequently found in tonsillitis and in areas to which the tonsils had been removed and the swabs from throats of patients suffering with measles showed a large percentage of *Streptococcus hemolyticus*, and of those many developed pneumonia of the streptococcio type. Out of 12 per cent. of pneumonias which developed following measles 90 per cent. were carriers of the hemolytic streptococcus, while in healthy people this organism was present in only six per cent. The hemolytic streptococci prepared the way for measles and later on for pneumonia. Sixty-one per cent. of the pleural exudates following contained the hemolytic streptococcus. In thirty-four autopsies of patients who died of pneumonia nine cases were of lobar and twenty-eight of the bronchopneumonic type. The hemolytic streptococcus was found in about eighty per cent. and was obtained in pure culture from bronchial pneumonia cases. In the lobar pneumonias the streptococcus was found in pure culture or combined with pneumococcus Type I. In only one pneumania case following measles was the pneumococcus Type I found alone. In pneumonia due to hemolytic streptococci the mortality was 82 per cent. It was important therefore to determine in a given case of pneumonia whether the cause of the organism was the pneumococcus or the streptococcus. Instead of dividing the pneumonias in the lobar and bronchial pneumonic types we should speak of pneumococcic and streptococcic pneumonia. All patients who were carriers of streptococci should have their tonsils removed; the milk supply should be sterilized and patients should be isolated or protected from one another by masks. The development of a streptococcic vaccine offered vast hopes for the successful treatment of that form of pneumonia.

The Pathology of the Pneumonia of the Army Camp.—Dr. WILLIAM G. MACCALLUM of Baltimore read this paper. He said a study of pneumonia in an army camp was undertaken during February and March. There were numerous cases of lobar pneumonia due to one or other type of pneumococcus. There were, however, still more cases of a peculiar bronchopneumonia due to infection with a hemolytic streptococcus. This condition frequently followed directly on measles which was very prevalent, but occurred also after scarlet

fever and in many cases in which there was no history of measles. The rapid interstitial infiltration of the tissues and organization of the exudate suggested the name interstitial bronchopneumonia for this type. Modifications of this lesion were found in cases of overwhelmingly violent infection. Combinations of lobar pneumonia and interstitial bronchopneumonia occurred. No septicemia had been found in the interstitial type of pneumonia except a few hours before death and after death. During life the germ was found in the sputum, in pleural effusions, and frequently in pericardial fluid. Streptococcic infection produced a marked congestion and inflammation of the respiratory tract; laryngitis with ulceration and tracheitis were common. Infection was rather localized, distant regions becoming involved by extension. Empyema was of extremely frequent occurrence. The conclusion as a result of the pathological studies was that though the infection caused by the hemolytic streptococcus was due to some predisposing cause such as measles, so far as pneumonia was concerned it was a distinct disease with as distinct a pathology as the primary pneumonia due to the pneumococcus.

Practical Consideration of Epidemiology Drawn from a Classification of Streptococci.—Dr. RALPH A. KINSELLA of St. Louis read this paper, in which he stated the previous work on classification of non-hemolytic streptococci indicated that this variety was highly variable. This variability seemed to depend on the existence of two opposite elements in the group, the individuality of any one member being determined by how much of one or the other element it displayed. Recent work on the classification of hemolytic streptococci indicated lack of variability, all strains studied being identical. The complement fixation reaction was the criterion on which the classifications were based, it being considered that the best basis for classification was an immunologic one, since bacteria owed their importance in medicine to their presence in man and their pathogenicity. His studies of the various groups of streptococci had demonstrated that no disease was shown to be due solely to one type of non-hemolytic streptococci, which lived under many conditions and were widely distributed, while the hemolytic streptococcus was rare in normal man, had a highly invasive capacity, was milk borne, and its presence in empyema was demonstrated in pure culture. The more widespread a bacterium was the greater was its variability and the less was its pathogenicity. This was best illustrated by the colon and typhoid bacilli. Of the pneumonias Type I had little variation, was not found in normal man, and was therefore highly pathogenic, while Type IV, which was widely distributed, was frequently found in normal man and was least pathogenic. The conclusion was that widespread heterogeneous bacteria were least invasive and rarely spread infection.

Dr. WELCH of Baltimore said one year ago such a discussion would have been an impossibility; a new problem had arisen; a new knowledge had come. When many cases of pneumonia appeared in camps they were thought to be entirely secondary to measles or due to other predisposing causes, as lack of warm clothing, cold weather, overcrowding, a great amount of dust and wind. Such was then the conception of the etiology of pneumonia; physicians were aware as to the peculiarities of pneumonia, but the experiences in the camps was something new. In this connection he wished to emphasize the importance of laboratory methods without which the problem could not have been solved. He wished especially to emphasize that it was the cooperation of the clinician, anatomical pathologist, and bacteriologist which formed the best method for the study of disease. The relationship of the streptococcus infection to the antecedent measles was not known yet. It was known that the same type of infection occurred in camps where there had been no measles. There was a great field open for further study, and the Surgeon General had appointed a pneumonia board which was to act as a clearing house for all the information obtained on the subject. The *Streptococcus hemolyticus* was still very little known; it was not known whether the germ, like the tubercle or the typhoid bacillus, was a definite type with a definite pathogenesis, or whether it had acquired a virulence by having passed through susceptible individuals. Measles might have enhanced its virulence, but now it was highly virulent by itself.

Dr. RUSSELL of Washington, D. C., said that the study of the mortality in the various camps presented many interesting features. Next to meningitis pneumonia was the principal cause of death. In Camps Pike, Beauregard, and Wheeler there was a mortality of 22 per cent. and over, while in other camps the mortality had been under 8 per cent. If, however, we considered the mortality with relation to the localities where the men came from it would be found that the high mortality camps were composed of men who came from Georgia, Arkansas, Alabama, and other Southern States, while the camps with the low mortality were composed of men coming from the Northeastern States. In camps where the death rate was low the rural population was low, as instanced in New England States, while where the mortality was high 78 per cent. of the men had come from rural communities. Pneumonia had occurred in troops who had not come from thickly settled cities. The picture was so clear that the condition was almost self-evident. Another interesting feature brought out was the fact that the more men were put on the sick list the lower was the mortality; hunting out light cases and caring for them early reduced the death rate. Camps Upton, Mead, and Logan had about the same mortality as New York, Baltimore, and Chicago, the cities where most of the men came from. In Southern camps the mortality had been higher than in the nearby cities. The explanation was that men coming from the country contracted various diseases very easily, while the men from the large cities appeared to be immune to measles and other disease and therefore had a low mortality. During the Civil War the same had been observed. Northern troops were healthier in Southern camps than the Southern troops no matter where located.

Dr. COLE of New York said he wished to emphasize one point about the two types of pneumonia: one was due to the pneumococcus and was endemic; the other, to the streptococcus, was epidemic, prevailing at a certain time and then disappearing. In animals streptococcus infection was a secondary disease and, fortunately, self-limited. The streptococcus was a variable organism and could become very virulent under certain conditions. Measles was a predisposing condition to streptococcic infection, after which the streptococci became more virulent. To prevent the spread of the infection early diagnosis and careful isolation of patients harboring streptococci were important, which in turn would tend to prevent the spread of measles. It was necessary to have hospitals for infectious diseases in every camp. Infectious diseases could not be treated successfully in a hospital organized on general basis. The two hospitals should be separate with separate personnel, should have observation wards and sufficient wards to be able to care for various kinds of infection. It was not so much a question of building as of organization.

Dr. BLISS of New York said that the subject had been very exhaustively discussed and his experience had been the same as in all camps. The percentage of empyemas was great, the mortality high, being usually due to pocket formation. The diagnosis for empyema had to be revised. Physical signs, blood counts, *x*-ray examinations could not be depended upon. If high temperature, pulse, and respiration continued after five or six days they looked for fluid, they did not spare the exploratory needle. High mortality after operation was often due to the spreading of the infection to the opposite side. They found daily irrigation of the pleural cavity with Dakin's solution following operations for empyema of great value. Costectomy was much preferable to thoracotomy. The treatment of pneumonia was along the customary lines but they used a standardized tincture of digitalis of which every 0.17 c.c. per pound of body weight produced the desired physiological effect within forty-eight hours; thus a man weighing 120 pounds received 20 c.c. of that tincture within the first forty-eight hours. Serum therapy for Type I pneumococcus was very beneficial in his experience, but with the other sera he did not have sufficient experience to be able to pass judgment. There appeared, however, to be a considerable lessening of toxic symptoms.

Dr. MCKENNA discussed this question from the surgical standpoint. He stated that after fourteen days

every case was examined with the *x*-ray and if pus was present surgical interference was resorted to. He had used the method of draining the pleural cavity instead of opening it and the results were very satisfactory. The draining of the pleural cavity was performed by the introduction of a No. 14 French catheter, by means of a trocar and cannula; if the fluid was found to be too thick a small quantity of Dakin's solution would dissolve it; as much as possible of the pus was removed and a corresponding amount of Dakin's solution was introduced. This procedure was repeated every three hours during the day and several times during the night. The fluid obtained from the pleural cavity was examined every day and cultures were made in order to determine the occurrence of mixed infections. This operative procedure minimized the danger of infecting the pleural cavity and prevented the collapse of the lung which occurred in the older operations. It could be repeated with ease and the fluid could be under constant bacteriological examination. Out of nineteen cases treated by this method all cleared up without sinus formation. In the presence of a lung abscess treatment with this method resulted in a sudden cough and a taste of the solution in the mouth. Out of 130 cases treated with the old method 42 per cent. died; the last nineteen patients treated with this method were still living. This form of treatment was not going to save all empyema cases, as a certain percentage were going to die no matter what the treatment was; but was of great value and had many advantages over the older methods.

Dr. DICK of Chicago said that he had had an opportunity to observe the case information in Camps Pike and Dodge; in the latter the nonhemolytic streptococcus was present in many lobar pneumonia cases. In Camp Dodge many patients suffering from pneumonia gave a history of exertion, as long hikes. Many cases of streptococcic pneumonia had suffered previously from coryza and bronchitis. The disease had not been carefully watched. The severity of the epidemic differed at different times, though the treatment was the same and one should not therefore lay too much stress on the methods of treatment because apparently more favorable results had been obtained by changes in treatment.

Dr. LICHTY of Pittsburgh said that he had observed two types of pneumonia during the past winter at the Mercy Hospital at Pittsburgh. One occurred in colored people who had come from the South; it was a typical lobar pneumonia. The patients were admitted to the hospital during the later stage of the disease and the mortality was very high. The social service should be informed so that they might instruct people who were moving from one part of the country to another. The other group of pneumonias occurred when cold began to break up and corresponded with the streptococcic cases observed in the Army camps. The course of the disease was atypical, there were many empyemas and the mortality was very high. This disease developed among the more intelligent part of the population but the people considered it grippe and did not take enough interest in it until too late. He thought laymen should be instructed as to the importance of the early signs of pneumonia just as they were taught in reference to cancer and appendicitis.

Dr. LOVEWELL of the Army said that his experience had been similar to that of the various authors of papers read. In Camp Snelling they had a number of cases of pneumonia during December, but nothing unusual was observed until during the month of February 800 cases had come on from Texas, after which he had seen respiratory diseases he had never seen before. Every physical sign obtained had been disproved by autopsy. In many cases the pleuritic exudate was of a gelatinous type making it impossible to obtain any by puncture. A large percentage of the cases developed tuberculosis. Another interesting point was the occurrence of purulent peritonitis and empyema in the same case.

Dr. RYAN of Des Moines wished to call attention to the usefulness of intravenous injections of glucose in cases of pneumonia. The subject had been discussed during the early part of the session by Dr. Litchfield, but his experience had been with 10 per cent. glucose to which sodium bicarbonate was added. Many excellent results were obtained by this form of treatment in pneumonia.

Later Results of Intraspinous Treatment of Cerebrospinal Syphilis Based on Four Years' Observation.—Drs. CLYDE L. CUMMER of Cleveland and RICHARD DEXTER of Toledo, Ohio, presented this communication which was read by Dr. Cummer. They said that their experience during the period of five years with the method of intraspinous treatment of neurosyphilis as suggested by Swift and Ellis was of great benefit in a certain type of cases. Careful clinical observation, together with laboratory findings, had convinced them that results could be obtained by the intraspinous method which could not be obtained in any other way. Some patients could not stand intravenous injections very well and tabetics often developed severe gastric symptoms under that form of treatment. Such cases frequently responded to the intraspinous method. They did not claim that the intraspinous method had done everything that was expected of that method nor was the method indicated to supersede other methods, but it was merely a good addition for certain types of cases. In the experience of the essayists, cases of tabes and of syphilitic meningitis were specially amenable to that form of treatment. Anatomical cure was not claimed in cases of tabes, but in the best cases the ataxia completely disappeared, they were free from gastric pains, and were able to attend to their previous occupations without any difficulty. In cases of paresis where degenerative changes had taken place this form of treatment was of no avail. In the early stages, however, it might be of benefit.

Dr. FORDYCE of New York said that the subject of neurosyphilis was a very important one. When the nervous system was involved during the floral stage of the disease it was very important to recognize the condition early, as, during that time, it responded well to the intraspinous method. Observation of twenty groups of familial and conjugal neurosyphilis had proven that a highly virulent spirochete was present which frequently affected the meninges during the early stage of the disease and even during the administration of salvarsan and mercury. In one case 960 cells per c.mm. were counted in the spinal fluid, in another 400 cells. Both patients had received intravenous and other form of syphilitic treatment; they were in a stage of delirium as a result of meningeal involvement; both recovered under intraspinous treatment. Early meningitic syphilis was specially favorably influenced by the intraspinous method, while the degenerative type of cases responded to the treatment less favorably. Disseminated and localized cerebrospinal types which did not respond well to other methods of treatment in his experience had responded well to the intraspinous treatment. Cases of optic atrophy might be arrested by the intraspinous method. There were no untoward effects as a result of that treatment if a proper technique was carried out. During the past four years he had had no bad results from this method.

The Relation of Mastoiditis to Acute Infectious Conditions.—Dr. GEORGE H. LATHROPE of Morristown, N. J., read this paper. He said that during the past winter Camp Shelby was invaded by an epidemic of pneumonia which was caused by the *Streptococcus hemolyticus*. Empyemas were few, but out of 300 pneumonia cases 123 cases of mastoiditis developed, on either one or both sides. The onset was rapid, beginning with pain one night, bulging of the drum the next morning, which was followed by incision; but within 72 hours the mastoid was involved and filled with thick pus. In some cases development of the disease was even more rapid. There seemed to have been a virulent type of germ which had a spcial predilection for the mastoid. The epidemic of mastoid disease seemed to have followed the epidemic of measles. Measles alone appeared to have been responsible for 38 per cent. of the mastoid cases. Bacterial examinations showed that of 132 cases 81 gave positive cultures. The cultures were from pus taken from the mastoid and not from the middle ear. The *Streptococcus viridans* predominated. Many patients with streptococcic infection died from a complicated basilar meningitis, which was proven also by culture. Twenty-seven cases were complicated by measles, respiratory disease, and otitis media. Contrary to the experience of other camps the streptococcus found in the cases which had followed measles was of the viridans type and not of the hemolytic. The obser-

vation of those cases led to the conclusion that Camp Shelby suffered from an epidemic of mastoiditis which was the result of a streptococcic infection, which, in turn, was the expression of a streptococcic invasion of other Southern camps. The predominating organism was the *Streptococcus viridans* and not *S. hemolyticus*, and measles apparently started the epidemic and contributed to its development.

Dr. FOWLER of the Army said that during a period of six months approximately 140 cases of mastoid disease had been operated upon at Camp Shelby, of which number very few were free from pus. It was his experience in the surgical department during four months, that when the patients were operated upon very early the results were good. Later cases developed complications, severest of which was basilar meningitis. There did not appear to be any definite pathway for the infection to travel from the mastoid to the basal meninges. Preventive treatment consisted in the early incision of the drum of any case of otitis, isolation, and disinfection of the wards. His opinion was that the occurrence of basal meningitis in cases of mastoid was probably accidental. The cumulative evidence of the cases observed was that a special virulent organism was present which was communicable and had a specific tendency to involve the mastoid.

Dr. SMALL of Chicago said he saw many cases of mastoid developed in Camp Pike. Quite a number developed after pneumonia and they were specially characterized by the absence of objective and subjective symptoms, being discoverd mostly upon autopsy. Middle-ear disease in pneumonia gave little pain until suppuration occurred. Complications following a careful operation for mastoid were frequent.

Dr. SCOTT of Iowa said the cases discussed resembled those frequently observed in children. Mastoiditis in children was usually diagnosed when the ear stood out too prominently. There was usually no pain and the otitis media was frequently overlooked. It seemed quite likely that the middle ear and the mastoid normally contained bacteria, but only under certain conditions the bacteria developed and produced disease.

Dr. POTTS of the Army said he was in Camp Shelby when the epidemic had developed and the experience in camp had been different from that he had seen in civil life. Formerly the onset was called to the attention of the physician by a great deal of pain which was usually followed by a reddened ear-drum, and which was an indication for a paracentesis of the drum, and a case was frequently obtained as the result. In Camp Shelby, however, the onset of mastoid disease was very rapid, frequently without any appreciable symptoms. In his opinion there was no question that the mastoid infection in Camp Shelby was of an epidemic type. The meningitis which frequently occurred in these cases was in his opinion due to general toxemia and was not transmitted from the mastoid.

Dr. LATHROPE, in closing, said that the pathway from the throat to the meninges had not been definitely proved. There was a direct path from the throat to the mastoid. He did not think that there were dormant bacteria in the middle ear or mastoid as Dr. Scott had suggested. In one case of basilar meningitis nothing was found except an infection of the ethmoid cells. The relationship of the meningitis to the mastoid deserved further study.

A Study of Diaphragmatic Movements in Acute Abdominal Inflammations.—Dr. LLEWELLYN SALE of St. Louis read this paper, in which he said that the limitation of the movements of the diaphragm had been previously recognized as an important sign, which bore a relationship to various inflammatory conditions in the neighboring organs. His first attention to that sign was called by a case following an appendical operation. There was absence of breath sounds on the left lower side which disappeared in several hours. A study of value of the limitation of diaphragmatic movements had been undertaken. All abdominal cases admitted to the surgical ward were examined for that sign. It was noted that in 16 cases of appendicitis the movements of the diaphragm on the right side were diminished and breath sounds were absent. In some cases where the diaphragmatic sign was positive, though diagnosis of appendicitis was doubtful, the cases turned out to be appendicitis, while in cases were a diagnosis of appendicitis was made but the diaphragmatic sign was negative, a normal appendix was found upon operation. In normal conditions there was practically no difference in the movements of the diaphragm on the two sides, but their continued investigations had shown them that there was a limitation on the right side of the diaphragm in cases of appendicitis, gall-bladder disease, and other inflammatory abdominal conditions. All the cases were studied by physical diagnostic methods and were verified by the fluoroscope. As to the cause for the limitation of diaphragmatic movement the essayist thought it might be due to the voluntary inhibition of the diaphragmatic muscle similar to the muscular contractions of the other abdominal muscles. The actual mechanism, however, of this phenomenon was by no means certain.

Dr. GUTHRIE of the Army said the new application of the diaphragmatic sign was very interesting; *x*-ray workers were used to look for it in thoracic diseases. They usually took it to be due to the disturbances of the phrenic reflexes. He thought there was nothing mysterious in the limitation of the movement of the diaphragm. It was due to a spastic reflex limitation similar to the reflex limitation of muscles in the case of an infected joint. He was satisfied that that was the proper explanation, but application of the diaphragmatic signs to abdominal conditions was a very useful and helpful procedure.

Dr. POTTINGER of California said that whenever there was any inflammation of the lungs the diaphragm was limited in its movements. In inflammation of the liver such a limitation of motion might be due to the phrenic nerve. In abdominal cases, however, he thought this was due to the lower intercostals which helped to innervate the diaphragm. Internal reflexes were very important and he hoped that more attention would be paid to them.

Dr. MCDONALD of Detroit stated that he had come across five or six cases which were operated upon for appendicitis but in which a normal appendix had been found, though typical symptoms of pain, tenderness, and rigidity of the abdominal muscles were present. In some cases basilar pleurisy was found. In one case a limitation of the diaphragm was observed in the screen, but he had also noticed a shadow and became suspicious of pleural effusion which later proved to be the fact, and he thought this should be remembered in connection with the positive diaphragmatic sign.

Dr. SALE, in closing, said he was glad of the information he had obtained through the discussion. He thought Dr. Pottinger's explanation as to the cause of the diaphragmatic phenomena had a great deal of value, though not explaining it completely. Dr. McDonald's point was very well taken, and he felt that in such conditions the diaphragmatic sign would be of very little help in making a diagnosis.

The Control of Cross Infections by Masking of Patients.—Dr. JOSEPH A. CAPPS of Chicago presented this communication, which was read by Dr. JAMES S. MCLESTER of Birmingham, Alabama. The epidemic of pneumonia and other streptococcic infections which had occurred in various camps raised the question of the prevention of the spread of respiratory diseases. It had been discovered that milk, cream, and ice cream were as important in spreading streptococcic infection as in spreading typhoid fever. In Camp Grant many diseases were traced to the milk, and when that was boiled the number of infections was decreased. The streptococcus caused more diseases than any other organism and certainly deserved active preventive measures. Many respiratory diseases were transmitted by nasal secretions, coughing and sneezing, and crowding in camps, receiving wards and ambulances. The best remedy for this was individual isolation by means of masks. They had carried out this experiment in Camp Grant with very satisfactory results. During the epidemic of grippe they first isolated the patients; later, due to lack of accommodations, they had placed some of the patients in the general wards. The result was that everyone developed grippe. Later on, under the mask system, they placed a number of grippe cases in the psychiatric department and no grippe cases had developed. Dr. McLester himself, who had carefully followed out the plan of the mask, had escaped grippe, though he had attended hundreds of cases and was

rather susceptible to this disease. In Camp Grant every case of contagious disease was masked. Everyone entering an ambulance or receiving ward was masked.

Dr. McLester further added that his personal experience had been the same as that of Dr. Capps. He had used the method at Camp Sheridan with very satisfactory results. They had an unusually large number of cases of coryza and bronchopneumonia. When the masked system was adopted these diseases were checked.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

January, 1918.

(Concluded from Vol. 93, page 1014.)

OBSTETRICS AND GYNECOLOGY.

1. Give the symptoms and the signs of pregnancy. Define positive signs.
2. Name the fontanels of the fetal head. How are they determined before birth? State the significance of the position in which they are found.
3. What is determined by urinary analysis during pregnancy?
4. Give the etiology and the treatment of inflammation of the mammary glands.
5. What gives rise to an atonic condition of the uterus? What conditions may be dependent on it? How should it be managed?
6. Give methods of resuscitation of an asphyxiated infant at birth.
7. Describe kraurosis vulvae. What are the sequelae of this disease? Give treatment.
8. Give the treatment of gonorrhea in the female. What are the sequelae of this condition?
9. With what conditions may inversion of the uterus be confused? Give the differential diagnosis.
10. Name the constituent structures of the perineum. Of what importance is the structure as a whole?
11. What are the various forms of new growths of the uterus? How are the benign growths differentiated from the malignant growths?
12. What is endometritis? Name the varieties of endometritis, giving the microscopic appearance of each.

SURGERY.

1. Give the signs and the symptoms of psoas abscess. State where it usually points.
2. Describe the treatment by posture and saline drip of a severe case of purulent peritonitis.
3. Differentiate femoral hernia from other conditions simulating it.
4. Give in sequence the symptoms of fracture of the skull with rupture of the middle meningeal artery.
5. What surgical procedure may be instituted in chronic pancreatitis?
6. Give a clinical picture of palmar abscess. State the precautions to be used in making incision for drainage in palmar abscess.
7. Discuss spinal anesthesia, naming the agents employed and giving the technic.
8. What are the special dangers to be avoided in treating burns near joints?
9. What is ectropion? Describe an operation for its relief.
10. Give the symptoms and the treatment of acute otitis media.
11. What are the serious objections to breaking up an impacted fracture of the femur? When should this be done?
12. What are Lane's kinks?

HYGIENE AND SANITATION.

1. What purposes are served by the registration of deaths?
2. Describe in detail the tuberculin test and explain its application in public health work.
3. What is a deodorant? Name two reliable deodorants.
4. What measures are necessary for the prevention of diphtheria in an orphan asylum?
5. Give in detail a method for the prevention of rabies in a person bitten by a mad dog.
6. Give in detail a method for determining the sanitary quality of well water.
7. Name three sanitary methods for the disposal of garbage on a farm.
8. What parasitic conditions may be produced by the ingestion of raw beef?
9. Give in full a list of the reportable diseases as established by the New York State Sanitary Code.
10. Name five metallic substances that may become factors in occupational diseases.
11. Name a disease that may be transmitted by the rat flea.
12. How may the presence of a typhoid carrier be detected?

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. *Subjective signs of pregnancy*, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heart beat, rate of growth of the uterine tumor.

The *positive signs of pregnancy* are such signs as are found in pregnancy only, and which are absolutely diagnostic of that condition.

Positive signs of pregnancy: (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation, and (5) the umbilical of funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

2. The *fontanels of the fetal head* are: (1) The anterior, or frontoparietal; (2) the posterior, or occipito-parietal. There are four other fontanels, two on each side, situated at the inferior angles of the parietal bones, but they are unimportant. They are determined before birth by the touch of the examiner's finger against the presenting fetal head.

In L. O. A. positions the small, posterior fontanel is found towards the left acetabulum. In R. O. A. positions the small, posterior fontanel is found towards the right acetabulum. In R. O. P. positions the large, anterior, fontanel is found towards the left acetabulum. In L. O. P. positions the large anterior fontanel is found towards the right acetabulum.

3. "The *urine* should be examined at regular intervals throughout pregnancy. This examination should be both chemical and microscopical, and made at least once a month for the first six months, and once a week during the last four. The presence of albuminuria, the evidences of toxemia, edema, renal insufficiency, or nephritis, demand daily examinations. This examination should determine the amount of urine passed in twenty-four hours, its specific gravity, the total amount of urinary solids, the percentage of urea, the presence or absence of albumin or sugar and of tube casts.—(Polak's *Manual of Obstetrics.*)

4. INFLAMMATION OF THE MAMMARY GLANDS. *Etiology:* Infection, generally due to handling; cracked or sore nipples and overactivity of the gland with retained secretion are predisposing causes.

Treatment: Prophylactic measures consists in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure. *Treatment* before suppuration occurs consists in sup-

porting the breast with a bandage, emptying the gland regularly with a breast pump, and applying a belladonna plaster over the gland to stop the secretion and allay the pain. Nursing from the affected breast should be stopped at once. When pus is present an incision should be made at once, or the abscess may burrow extensively and riddle the breast. The incision should be made in a line radiating from the nipple, so as not to cut the ducts; it should be free, and all pockets opened up with the finger. Then a large drainage tube is inserted and shortened daily, as the wound heals by granulation. If necessary, several incisions are made.

5. *Autonic condition of the uterus* may be *caused* by: Debilitated constitution, exhausting disease; uterus weakened because of congenital malformation, inflammation, or too frequent child-bearing; tumors of the uterus or neighboring tissues; displacement of the uterus; age (pregnancy in an old primipara), hydramnios; twin pregnancy; fright or mental emotion.

It may predispose to delayed labor, prolonged labor, lacerations, infection, post-partum hemorrhage, and subinvolution.

Treatment consists in removing the cause if possible; the bladder and bowel should be emptied; opium, morphine and chloral may be given so that the patient may get a little sleep, at the same time food may be administered; the uterus may be massaged through the abdominal walls; hot vaginal douches are sometimes helpful; the vagina may be distended with a rubber bag; if the membranes are ruptured a Champetier de Ribes bag may be placed in the lower part of the uterus; an anesthetic may be necessary; quinine, strychnine, and ergot have been recommended by some, and condemned by others; the newest remedy is pituitrin, which may be injected into the muscles in doses of from one to one and a half cubic centimeters, provided that the cervix is dilated and that there is no obstruction to delivery.

6. *Methods of resuscitation of an asphyxiated infant at birth.*—In every case, foreign matter must be removed from the air passages; then any of the following may be tried: (1) *Holden's method* of direct insufflation with oxygen. (2) The use of the *pulmotor.* (3) *Direct* (mouth to mouth) *insufflation.* (4) *Schultze's Method*—For inspiration the child should be suspended by the shoulders, face from the operator, by placing an index finger in each axilla, holding the thumb in front and two fingers extended over the posterior aspect of each shoulder, expanding the chest, while the head is kept steadied and extended between the ulnar surfaces of the hands. For expiration the position is inverted by swinging the trunk and lower limbs upward and toward the operator's face, flexing the body in the lumbar region. *The first movement should be one of expiration,* which helps to rid the trachea of mucus. The objections to this method are, first, the chilling of the body; second, the shock involved, so that in feeble infants, if used at all, it must be done with great caution. This, and direct insufflation with oxygen, or by mouth to mouth, are the most effectual methods in asphyxia of the newborn. (5) *Sylvester's Method.*—The child is placed in a supine position, with the head well extended by a fold of blanket under its neck. For inspiration, the arms are drawn well above the head; for expiration, they are placed by the sides and the thorax gently compressed. The value of this method is increased by making forward traction on the tongue during inspiratory movement. (6) *Byrd's Method.*—The child is held supine upon the hands of the operator at right angles to the forearms. For inspiration the radial borders of the hands are lowered. For expiration they are raised. The child is successively folded and unfolded. (7) *Laborde's Method.*—With the child lying in a supine position on a table, or in a warm bath, with the head extended, gentle intermittent traction is made on the tongue about eighteen times to the minute. (8) When respiratory movements have been established *but remain persistently feeble,* a weak Faradic current, one pole of which is applied to the nuchal region and the other over the epigastrum, combined with the continued inhalation of oxygen, may induce deeper and stronger respiratory efforts. (9) Should all of the foregoing methods fail, and the fetal heart, however slow, continue to beat, an injection into the umbilical vein of 30-50 cm. of sterile normal salt solution, containing 0.5 per cent. of fructosate of sodium, may be given. The salt solution dissolves CO_2.—(From Polak's *Manual of Obstetrics.*)

7. KRAUSOSIS VULVÆ is a condition in which the tissues of the vulva undergo atrophy and contraction. The patient may suffer little or no inconvenience, but as a rule she complains of itching, burning, pain, impossibility of coitus; there may be a discharge, or the parts may be dry. The vulvovaginal orifice is narrowed, the pubic hair is dry and broken, and the parts look shiny and smooth. The *sequelæ* are dyspareunia, dystocia, extensive lacerations in labor, and general discomfort. *Treatment* consists in the application of sedative and cooling lotions, or an ointment containing opium or cocaine; nitrate of silver and phenol have been recommended. Operative procedures, such as forcible dilatation, cauterization, and excision, have afforded relief.

8. *Treatment of gonorrhea in the female:* Rest, if possible, in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart), or of potassium permanganate (1 per cent. solution); the douche is to be taken in the recumbent position. *Sequelæ:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands.

9. *Inversion of the uterus may be confused with:* Procidentia, or polyps, or myoma of the uterus.

The *differential diagnosis* is shown in the following tables (from Dudley's *Principles of Gynecology*):

COMPLETE INVERSION OF UTERUS.	UTERINE POLYPUS OR MYOMA
1. No pedunculated attachment to uterus.	1. Attached to uterine wall by broad surface or by narrow pedicle.
2. Uterine cavity being obliterated, sound can be passed but short distance, in incomplete and not at all in complete inversion.	2. Sound passes by the side of the mass through external os far into uterine cavity.
3. Vaginal or rectal conjoined examination shows a ring or depression where the uterus should be, and fails to show the uterus above the vagina.	3. Uterus felt above vagina.
4. The inverted uterus is a symmetrical pyriform body.	4. Not usually symmetrical and may be very asymmetrical.
5. Orifices of the Fallopian tubes usually demonstrable.	5. Not present.
6. Muciparous glands of the uterus present and microscopically demonstrable.	6. Not present, or if present less perfectly developed.

INCOMPLETE INVERSION OF THE UTERUS	INTRA-UTERINE MYOMA
1. The uterine cavity as measured by the sound will be diminished.	1. Cavity enlarged.
2. Development sudden.	2. Development gradual.
3. Bimanual examination shows rig-like depression in wall of uterus.	3. Uterus symmetrical or asymmetrical, but no ring-like depression.
4. Usually dates from parturition.	4. No parturition.

INVERSION OF UTERUS.	COMPLETE PROCIDENTIA
1. The protruding mass is wider below than above.	1. Mass wider above.
2. External os uteri absent and tubal orifices present at lower end of mass.	2. External os present and tubal openings absent.
3. Sound in urethra goes upward into bladder. *Exception.*—When the vagina is concurrently inverted the sound may pass downward.	3. Sound goes downward into anterior portion of mass.

10. The *perineum* or *pelvic floor* is composed chiefly of fascia, muscles, and connective tissue. Its superior surface is lined by peritoneum. Next below, and in close contact with the peritoneum, comes the "internal pelvic fascia." Immediately below the internal pelvic fascia are two thin muscles, viz.: (1) The *levator ani*, each half of which arises from the body and horizontal ramus of the pubes and from the arcus tendineus, and passes downward and inward to meet its fellow of the opposite side in the median line, where it is inserted into a tendinous raphe extending from the coccyx to the rectum, while some fibers pass between and to the sides of the bladder and rectum, and to the vaginal and rectal sphincters. (2) The *coccygeus*, which is a narrow, triangular slip, situated parallel with and posterior to the levator ani, closing in a little space which the latter muscle failed to cover. Below these muscles the pelvic floor is further strengthened by the *perineal fascia*. Its posterior portion consists of a single layer, while its anterior part is divisible into three layers. Within these latter layers are lodged the pudic vessels and nerves, and the superficial muscles of the perineum. These muscles are the *constrictor vaginæ*, the *sphincter ani*, and the *transversus perinei*, and to these structures must be added the integument and the very numerous interstitial layers of elastic connective tissue, which latter weld the parts together and add strength and elasticity to the whole fabric.—(From King's *Obtetrics.*)

The perineum helps to support and compress the pelvic viscera, enabling them to maintain their normal relationship. It also surrounds and supports the lower end of the rectum, the vagina, and the urethra, and so enables them to perform their functions properly.

11. *New growths of the uterus:* Cysts, adenoma, polyps, myoma or fibroid, sarcoma, carcinoma, endothelioma, papilloma, deciduoma malignum.

Malignant growths of the uterus are diagnosed by the history, symptoms, physical signs, and microscopic examination. It is a disease of advancing years, and generally occurs after the menopause; nulliparæ and multiparæ are equally liable. The chief symptoms are hemorrhage and discharge with an offensive odor, pain, and cachexia. The cervix is soft, the uterus enlarged, and tender. The uterus must be curetted, and the scrapings examined by the miscroscope.

12. *Endometritis* is an inflammation of the uterine mucosa. The *varieties* are: Acute and chronic; noninfectious and infectious; the latter are septic, gonorrheal, tuberculous, and syphilitic.

Septic endometritis: There is a necrosis of the superficial endometrium and a barrier of granulation cells in the deeper layers of the mucosa. The necrotic endometrium is exfoliated, the microorganisms perish (except in the puerperium, when the cocci may penetrate the lymph channels, blood spaces and myometrium). *Gonorrheal endometritis* is an inflammation of the mucous membrane in which gonococci are found in and under the epitnelium, and penetrating the myometrium perhaps to the perimetrium. The surface epithelium is exfoliated or shows a transitional stage to the many layered squamous type. The glands are unaltered except that they are distended with secretion, and the cells may be increased in number. There is edema and a round cell infiltration of the interglandular tissue with a few pus cells. There is also a cellular infiltration of the myometrium, which may lead to abscess formation in the uterine wall. *Tuberculous endometritis* may be miliary, interstitial or ulcerative. Tubercle bacilli are the infecting agents, but their presence is difficult or impossible to demonstrate. The interior of the uterus may be covered with a caseous material. The underlying layer of surface cells is unbroken. Beneath them are masses of epithelioid cells, occasionally giant cells, or round cell infiltration, and possibly typical tubercles. There may be a caseous mass in the myometrium.

Chronic hyperplastic endometritis. The glands may be increased in number, acquiring a corkscrew form, and display a dilatation of the gland-spaces, with excrescences of epithelium in their lumen. There is also a proliferation of epithelium upon the surface of the endometrium, but nowhere a duplication of the single epithelial layer in the glands or on the surface, except in elderly women. In the interstitital form there is at first a round cell infiltration of the interglandular connective tissue. The glands are widely separated and compressed; there may be exfoliation of the surface epithelium; in the later or chronic stage the round cells are converted into spindle cells; scar tissue is formed; the glands are so compressed that they atrophy and disappear; the uterine mucous membrane is reduced to a single layer of epithelial cells on the surface of the uterine cavity. There is frequently a mixed form of interstitial and glandular endometritis, and varying gradations may be observed between the purely glandular and the interstitial hypertrophy.—(From Hirst's *Gynecology.*)

SURGERY.

1. *Signs and symptoms of psoas abscess:* "There may be none, old unsuspected psoas abscess being often found at the autopsy. Early symptoms depend upon irritation of the lumbar nerve roots—namely, sciatica, cruralgia, or neuralgia of the anterior crural. Aching across the hip and back and the base of the sacrum; cramp, and at times paralysis. Inability to extend the thigh. Children merely complain of a pain down the thigh, and always carry it flexed. Deep pressure in the abdomen, along the semilunar line, reveals a vertical, sausage-shaped, tender, fluctuating, elastic tumor (mistaken for loaded bowels, but which does not roll from under the fingers). It may or may not reach Poupart's ligament and may be accompanied by a tumor of similar character in the iliac fossa. The abscess may run its course without any subjective symptoms, the extra-abdominal tumor first attracting attention. When extra-abdominal the usual physical signs show it to be abscess; and the impulse on coughing that it has intra-abdominal connection; combined pressure above Poupart's ligament and over the tumor in, *e.g.*, the thigh, reveals fluctuation. Psoas abscess is most likely to be overlooked when symptoms of spinal or sacroiliac disease are not coexistent."—(Heath's *Dictionary of Surgery.*)

Psoas abscess usually points in the upper and anterior part of the thigh, below Poupart's ligament, external to the femoral vessels; but occasionally it may point above Poupart's ligament, or over the great trochanter of the femur, or over the iliac crest into the gluteal region, or elsewhere.

2. *In case of severe purulent peritonitis,* "the patient is placed in the 'Fowler position,' that is, with the head of the bed raised about eighteen inches, or he is propped up on pillows in the sitting posture, so that any fluid in the abdomen may gravitate into the pelvis. Saline solution should be introduced in sufficient quantity to restore the blood pressure and to increase the excretory action of the kidneys and skin. It may be run continuously into the rectum through a catheter and rubber tube connected with a douche-can placed at a level of about six to twelve inches above the pelvis; the solution at a temperature of 100° Fahr., is allowed to flow at the rate of about three-quarters of a pint per hour."—(Thomson and Miles' *Manual of Surgery.*)

3. A *Femoral Hernia* may be mistaken for an inguinal hernia, an enlarged lymphatic gland, a lipoma (especially in women), a psoas abscess, and a varix of the saphena vein.

From an *enlarged gland* diagnosis is made by the absence of an impulse on coughing, by the increased feeling of resistance, and by the irreducibility of the gland. An enlarged gland is, however, often found

associated with a femoral hernia. In a fat subject diagnosis between a gland and an omental hernia may be very difficult.

The *lipoma* is differentiated by its mobility and absence of attachment. There is no impulse on coughing, and it is dull to percussion. Again the difficulty is increased in cases of omental hernia.

A *psoas abscess* is reducible, and has an impulse on coughing. It returns to the abdomen much more slowly than the hernia, and never with a gurgle. It lies to the outer side of the femoral artery, while the hernia is internal, and fluctuation can often be felt between it and the iliac fossa. If there is doubt the spine should be carefully examined.

A *varix of the saphena vein* has an impulse on coughing, and disappears on recumbency. The impulse on coughing is, however, quite different to that of a hernia. A varicose saphena vein is generally associated with varicose veins *below the knee*, the thigh being free.—(*Aids to Surgical Diagnosis.*)

An *inguinal hernia* has its neck *above* Poupart's ligament; a *femoral hernia* has its neck below it.

4. *Fracture of the skull with rupture of the middle meningeal artery.*—"After the injury there is generally a 'free interval,' in which the patient recovers to some extent from the concussion, and may even appear to be well. If there has been no concussion he may even have gone about his work for a time, and severe bodily or mental excitement have caused recurrence of the bleeding. If shock is a prominent sign, it generally diminishes with cessation of bleeding, on account of circulatory weakness and formation of thrombus in the vessel, or of excess of intracranial pressure. This recovery may set up bleeding again, and the same series of symptoms are repeated. As effusion increases symptoms of compression begin, with unconsciousness, slowing of the pulse, and stertor. The most common local signs are paralysis of the head and upper limbs, and, in left-sided injuries, aphasia. Owing to the small size of the branches of the middle meningeal artery, hemorrhage is not so severe over the upper Rolandic area, hence the trunk and leg muscles are less severely implicated. Impairments of sensation are not as a rule easily determined, on account of the mental condition of the patient, but they are useful when positively noted. The general course is that of progressive compression of the brain."—(Buchanan's *Handbook of Surgery.*)

5. *Surgical procedures in chronic pancreatitis* may include: Removal of gallstones if any are present; cholecystostomy (for indirect drainage of the pancreas), cholecystenterostomy.

6. In *palmar abscess* the hand is swollen, both on the dorsum and on the palmar aspect. The fingers are bent and stiff. The pain is severe, and constitutional symptoms are marked. If the thumb and little finger are involved (or their synovial sheaths) the forearm may be affected as well as the hand.

In making incision, the cut should be below the palmar arches, in the line of the metacarpal bones, and the sides of the fingers should be avoided if possible. If incision has to be made above the palmar arches these latter are to be avoided.

7. *"Spinal anesthesia* is produced by the injection of a local anesthetic into the subarachnoid space. Cocaine and eucaine are seldom used at the present time. Stovaine has a strong affinity for the motor nerves, and may, in high anesthesia, cause paralysis of the respiratory muscles. Tropacocaine and novocaine possess less of this affinity, hence are safer; the usual dose is from one-half to one grain. The solution is prepared by dissolving the drug selected (previously sterilized) in cerebrospinal fluid, which is drawn into the syringe containing the anesthetic, after the introduction of the needle into the subarachnoid space. In order to make the solution of a higher specific gravity than the spinal fluid and so remain in the lower part of the spinal theca, Barker uses distilled water 1 c.c., glucose 0.05 gram, and stovaine 0.1 gram. The syringe should be boiled in plain water, as the soda solution employed for other instruments may diminish the efficacy of the anesthetic. The patient lies on the side, or assumes the sitting posture; in either case the back should be bent forward in order to increase the space between the vertebral arches. The operator places one finger upon the spine of the fourth lumbar vertebra, which is on a line between the two iliac crests, and enters the needle fitted with a stylet, just below and to the right of this point, in a slightly upward and inward direction, until the dura has been punctured, which in the adult is usually at a depth of two and one-half inches. The stylet is withdrawn and 1 dram of the cerebrospinal fluid allowed to escape. The anesthetic solution is then slowly injected, the needle withdrawn, and the puncture sealed with collodion. The patient is then placed in proper condition for operation, but never should the head and shoulders be on a lower level than the lumbar vertebræ, as the fluid may gravitate towards the medulla and cause respiratory paralysis. Anesthesia results in about five minutes and lasts from one to three hours or longer. No attempt should be made to induce anesthesia above the diaphragm. Headache, nausea, and vomiting are frequent sequelæ, and evidence of transient and permanent cord injuries has been noted. The chief dangers are infection, injury to the cord, and poisoning from the anesthetic employed. The mortality has been estimated at 1 in 200. From what has been said it may be gathered that the method is destined to pass into desuetude."—(Stewart's *Manual of Surgery.*)

8. *In treating burns near joints, the special dangers to be avoided* are: The formation of cicatricial contractions, deformities, loss of motion of the joint.

9. *"Ectropion* is an eversion of the lid with exposure of more or less conjunctival surface. It may affect the upper or the lower lid, or both. *The V-Y operation* (*Wharton Jones*).—A V-shaped incision is made with the apex directed away from the palpebral margin, the incision including the cicatrix. The skin is freed from underlying parts, not only in the V-shaped area, but also to either side. The V-shaped area is slid upward until slight inversion of the lid margin is produced. The margins of the incisions are then brought together by sutures in such a manner that the figure Y results."—(May's *Diseases of the Eye.*)

10. *Acute catarrhal otitis media* is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the eustachian tube. Inflation and aspiration of the middle ear and syringing and douching the nares and nasopharynx must be avoided. A moderate spray of Dobell's solution may be used. If pain is present, dry heat, in the form of hot-water bottle, hot stone wrapped in flannel, etc., may be applied. A few drops (100), warmed, of a carbolic acid solution (1:40), or one of formalin (1:2000), may be instilled into the ear.

11. *The objections to breaking up an impacted fracture of the femur* are: (1) Such a procedure might cause a gap between the fragments, and so hinder repair; (2) it might cause undue mobility between the fragment, which would also hinder repair. The *impactions should be broken up* only when the patient is young and healthy and active; and if the deformity is great, and there is excessive shortening.

12. *Lane's kinks* are bends or twists of the intestine which are due to the upright position maintained by the body and also to the descent of the cecum from its early embryonic position: adhesions attached to the lower end of the ileum, or accessory peritoneal bands, are often responsible for the condition.

HYGIENE AND SANITATION

1. *Purposes served by the registration of deaths.* "Death registration serves a number of highly important purposes. Its functions are legal, economic, and social. Death registration is useful in preventing and detecting crime through the restrictions placed upon the disposal of dead bodies. It serves as evidence in the inheritance of property and in the settlement of life insurance contracts and policies. Death registration makes it possible to show by mathematical computations and statistical methods the extent and rate of change in population produced by deaths; the average duration of life, and, to the extent that the certified causes of death have been correctly stated, the relative frequency with which the several causes produce death. Death statistics by comparison with birth statistics give useful information regarding popu-

lation increase or decrease."—(Rosenau's *Preventive Medicine and Hygiene.*)

2. "The *tuberculin reaction* has been made a cardinal feature in the diagnosis of tuberculosis in cattle, and to some extent in man. Its chief practical application is in detecting the disease in dairy cows. The test on cows is made by injecting subcutaneously from 20 to 40 centigrams of tuberculin and noting any change in the temperature of the suspected animal. The normal temperature should be taken every two hours on the day prior to the injection, and after the injection should be taken on that day and on the following day at least every two hours. The normal temperature of the cow may vary considerably, and should always first be determined; a rise of from 1.5° to 3° C. warrants the inference that the animal is tuberculous; the tuberculin reaction has been often controlled by autopsy, and for all practical purposes is specific and unequivocal. The information afforded by a positive outcome, as a rule, can be relied on implicitly, but a negative reaction is not always proof of the absence of infection. Failure of the test is most likely to occur in advanced and clinically recognizable cases."—(Jordan's *Bacteriology.*)

3. A *deodorant* is a substance which is able to destroy or to neutralize the disagreeable odors which result from the putrefaction or fermentation of organic matter. *Two reliable deodorants:* Charcoal and formalin.

4. *Measures necessary for the prevention of diphtheria in an orphan asylum:* The isolation of all cases and carriers; all who show cultures containing organisms which morphologically resemble the diphtheria bacillus should be isolated, whether the strains are virulent or not. Cultures should be taken from both nose and throat. Convalescents should not be released from quarantine until at least two cultures taken from both nose and throat are negative. All persons within the institution, both inmates and administrative force, should then be tested to the Schick reaction. Those reacting positively should be given a prophylactic dose of diphtheria antitoxin (1000 units). The immunizing dose may be repeated every ten days or two weeks as long as the danger persists. Those who react positively to the Schick test may be immunized with a toxin-antitoxin mixture. Each cubic centimeter of the mixture contains from 80 to 90 per cent. of the L+ dose of toxin, and one unit of antitoxin. One cubic centimeter of this mixture is injected subcutaneously and repeated three times at intervals of six or eight days. The results as determined by the Schick reaction produce an immunity in about 25 to 30 per cent. of injected individuals within four weeks; the remainder react slowly, in four months to two years. In addition to the above-mentioned measures care must be taken that the infection is not spread by the use of cups, spoons, dishes, toys, towels, handkerchiefs, and other articles used in common. The infected discharges should be rendered harmless at the bedside, and all objects that come in contact with the discharges from patients or carriers should be disinfected. A general fumigation with formaldehyde may be practised, but in a well-ordered institution special cleanliness of floors, walls, and other surfaces, will suffice.—(From Rosenau's *Preventive Medicine and Hygiene.*)

5. *To prevent rabies in a person bitten by a mad dog:* The bite should be cauterized with the actual cautery, with fumic nitric acid, or pure carbolic acid followed by alcohol. "*Preventive inoculation*, which was originated by Pasteur, consists of intensifying the action of the virus by passing it through successive rabbits, until the period of incubation is reduced to seven days. The spinal cords of these rabbits are preserved in dry air for twelve to fifteen days, and a small quantity of the emulsion prepared by triturating the cord with physiological salt solution is injected into the person to be immunized. This is followed by injections on the following days of emulsions made from cords which have been preserved for fewer and fewer days, the contained virus being stronger and stronger. This method has given the most gratifying results, and where it is undertaken promptly is rarely unsuccessful."—(Gardner and Simond's *Practical Sanitation.*)

6. "A complete sanitary analysis of water includes: (1) A *physical examination* to determine odor, turbidity, color, and taste; (2) a *microscopic examination* to determine the number and character of particles in suspension, especially algæ; (3) a *chemical analysis* to determine the nature and amount of chemical impurities; (4) a *bacteriological examination* to estimate the number and kind of bacteria; (5) a *sanitary survey* of the watershed, including the methods of collecting, storing, handling and distributing the water; and (6) *clinical experience*, which, after all, is the final test, for water may contain impurities that are not recognizable by any other method."—(Rosenau's *Preventive Medicine and Hygiene.*)

7. *Three sanitary methods for the disposal of garbage on a farm:* The garbage may be (1) burnt, (2) buried, or (3) fed to the hogs.

8. *Parasitic condition which may be produced by the ingestion of raw beef:* Tapeworm infection (Tænia saginata).

9. *Reportable diseases of the New York State Sanitary Code:* Anthrax; chickenpox; Asiatic cholera; diphtheria (membranous croup); dysentery, amebic and bacillary; epidemic cerebrospinal meningitis; epidemic or streptococcus (septic) sore throat; German measles; glanders; measles; mumps; ophthalmia neonatorum; paratyphoid fever; plague; poliomyelitis, acute anterior (infantile paralysis); puerperal septicemia; rabies; scarlet fever; smallpox; trachoma; tuberculosis; typhoid fever; typhus fever; whooping cough.

10. *Five metallic substances that may become factors in occupational diseases:* Lead, mercury, arsenic, brass, and copper.

11. *A disease that may be transmitted by the rat flea:* Plague.

12. *The presence of a typhoid carrier may be detected:* (1) by making a Widal test on all suspected persons; this reaction is almost constantly present in the blood of typhoid carriers. (2) The bacilli should then be sought in the urine and feces of those giving a positive Widal reaction.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

BULLETIN OF THE MASSACHUSETTS COMMISSION ON MENTAL DISEASES. Vol. I, Nos. 1 and 2. Published Quarterly. 303 pages. Illustrated. Published by Wright & Potter Printing Company, State Printers, 32 Derne Street, Boston.

LES PLAIES DE GUERRE ET LEURS COMPLICATIONS IMMÉDIATES, LEÇONS FAITES À L'HOTEL-DIEU. Par HENRI HARTMANN. 200 pages. Illustrated. Price, 8 francs. Published by Masson et Cie., Paris.

AMBULANCE DE "L'OCÉAN" LAPANNE. Travaux publiés sous la Direction du Dr. A. DEPAGE, Dr. A. P. DUSTIN et Dr. G. DEBAISIEUX. 381 pages. Illustrated. Price, 14s. Published by Masson et Cie., Paris.

NINE HUMOROUS TALES. By ANTON CHEKHOV. 60 pages. Price, 25 cents. Published by the Stratford Company, Boston, Mass.

NORMAL AND PATHOLOGICAL HISTOLOGY OF THE MOUTH. By ARTHUR HOPEWELL-SMITH, L.R.C.P., Lond.; M.R.C.S., Eng.; L.D.S., Eng. Vol. I, Normal Histology. 345 pages. Illustrated. Price, $4.50. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

THE MEDICAL CLINICS OF NORTH AMERICA. March, 1918. 1,456 pages. Illustrated. Price per year, $10.00. Published bi-monthly by W. B. Saunders Company, Philadelphia and London.

CANCER, ITS NATURE, CAUSES, DIAGNOSIS, AND TREATMENT. By ROBERT HOLMES GREENE, A.M., M.D., F.A.C.S. 172 pages. Price, $1.50. Published by James T. Dougherty, New York.

DIABETIC MANUAL. By ELLIOTT P. JOSLIN, M.D. 187 pages. Illustrated. Price, $1.75. Published by Lea & Febiger, Philadelphia.

RECLAIMING THE MAIMED. By TAIT MCKENZIE, M.D. 128 pages. Illustrated. Price, $2.00. Published by the Macmillan Company, New York.

THE SOLDIER AND TUBERCULOSIS.*

BY EDWARD O. OTIS, M.D.,

BOSTON.

WE are all familiar with the efforts that have been and are being made to eliminate tuberculosis from the Army before the soldiers are sent overseas. The startling statements with regard to the extent of tuberculosis in the French Army, since shown to be greatly exaggerated, were an additional incentive to such efforts. Both phthisiologists of long experience and those recently trained by short intensive courses in the diagnosis of tuberculosis have been engaged in the work. The plan was as comprehensive as the army itself, namely, to examine every soldier in camp. Two classes of cases came under consideration: One, the open active cases which were to be rejected without question; and the other, the closed, latent, or arrested cases which were either rejected or referred for some service in the non-combatant force at home or abroad.

Excellent rules and formulæ have been given the examiners as to methods and procedure in the examinations, but it must be confessed that the judgment and experience of the seasoned diagnostician transcends any fixed rules, and he will make the diagnosis, when it can be made, in his own accustomed way better than when he is restricted or hampered by the methods of other men or by rules prepared by anybody else who may be his equal in skill and experience but who also arrives at his results in his own personal way.

Obviously but few of the evident open progressive cases will be, or in my experience were found, for such are generally detected either by the exemption board if drafted men or by the examining surgeon if volunteers. Some slip by, however, through either the carelessness or the inadvertence of the examiner, as the following cases illustrate.

Quite recently a young man came to me whom I had seen eleven years previously and who then had unmistakable signs of tuberculosis. He now had active advanced disease, the left lung entirely involved and likewise the upper lobe or more of the right lung. He had so little free lung that any exertion caused dyspnea. Moreover, he had a temperature of 101.2°. A short time previously, upon April 5 of this year, he was examined by the exemption board of his city and placed in Class A, "qualified for special and limited service." It is difficult to imagine what kind of "special service" a man with far advanced active tuberculosis could perform.

A young man twenty-five years old came to me in the uniform of one of the services, in which the physical examination is supposed to be particularly rigid. Five years previously I had been called into the country to see him and found him in the third stage of active pulmonary tuberculosis, with extensive infiltration and softening throughout the right lung and inactive disease in the left and with the usual symptoms of active tuberculous infection. The examiner had evidently neglected to make him cough on auscultation; if he had done so, I am sure he would have detected rales in the left lung. On ordinary respiration, however, it was easy for one not especially experienced to overlook the condition, for the man in appearance was perfectly healthy and well developed.

On the other hand, a young man from Vermont came to me who had been anxious to enlist and who had been rejected by the examining surgeon of the Army on account of alleged tuberculosis. I was unable to find any physical evidence of the disease; the *x*-ray plate was negative, and he had a lung capacity of 250 cubic inches. I gave him a statement to this effect, and with this and his Roentgen-ray plate he appeared again for examination, and was again rejected with the statement that the lungs were suggestive of a pretuberculous stage. The man was somewhat under weight and rather poorly developed, it is true, but, in my opinion, there was no good evidence of tuberculosis. While we are taking every means of eliminating tuberculosis from the Army it would seem to be the part of wisdom to employ equally efficient means to prevent men from being rejected on account of tuberculosis without the clearest evidence of its existence.

As in civil life the border line cases or suspects present many difficulties and the decision for rejection or detention in the service must mainly be made upon the physical findings from the lack of time for observation and the rapidity with which the cases have to be determined. With the most experienced diagnosticians differences of opinion will occur as they always have occurred. It is inevitable that some non-tuberculous men will be rejected and some tuberculous ones passed.

The question is how to reduce so far as may be the possibilities in the case to probabilities or certainties. Careful re-examinations by several experts and a comparison of observations and opinions and the aid of the Roentgen ray may result in a definite decision. There is, and probably always will be, a difference of opinion as to the decisive value of Roentgen-ray revelations or lack of them. Many phthisiologists will, I think, agree with me that it is

*Read at the Annual Meeting of the American Climatological and Clinical Association, Boston, June 6, 1918.

unsafe to base one's decision upon this evidence alone, and many will differ as to which set of observations should be given the preponderance when they differ—those derived from the physical examination or those from the *x*-ray examination. For example, Capt. A. of the Medical Reserve Corps came to me for examination with the history that while on duty at one of the southern camps he began to show signs of failing health, and on being examined by a physician of experience in tuberculosis he was declared to be tuberculous and sent home on a furlough. I examined him several times at intervals and always found persistent fine rales at the left supraspinous fossa. In consequence of this and from the previous history I advised his resignation from the service, and accordingly he went to Washington to accomplish it with a statement from me as to my diagnosis. This, however, was not regarded as authoritative, and he was sent to the Walter Reed hospital for examination by an army surgeon of sanatorium experience. He was told that he had extensive disease in the left lung as well as some in the right one. Upon two separate occasions I had an *x*-ray taken by one of our most accomplished Roentgenologists, now a major in the service and the head of one of the Roentgenological army schools, who told me that in both instances the plates were negative and showed no evidence of tuberculosis. Which set of evidences shall we take, the physical findings, which, in my opinion and that of the two other examiners, indicated tuberculosis, or the evidence of the *x*-ray which showed no disease? In the one case the officer would be discharged, as he was, and in the other retained in the service.

Again a lieutenant in the M. R. C. came to me, somewhat perturbed, because, while in the Roentgenological School for Officers, he had an *x*-ray plate of his own chest taken which indicated some tuberculous infiltrations. I could detect no evidence of disease from the physical examination and evidently the examiner for entrance into the Army did not, and so far as the man knew he was in robust health. If the decision of his acceptance or rejection from the Army had depended solely upon the *x*-ray revelations he would have been rejected. I strongly favor, however, Dr. Brown's suggestion that roentgenograms be taken of at least 10,000 men of the National Army "for the benefit," as he says, "of future drafts and for the benefit of the whole civil population." A comparison of the physical signs, or lack of them, and the roentgenological findings of this large body of men would be most interesting and instructive. So far I am inclined to agree with Hawes[1] that "in adults the *x*-ray may give a certain amount of confirmatory evidence but never enough on which alone to base a diagnosis."

When one comes to the inactive, latent, or arrested cases, the "old tops," with no symptoms and only physical signs—and those perhaps indefinite—to indicate that a tuberculosis infiltration or fibrosis exists, the difficulties in both diagnosis and decision are often as great as in the border line cases. In the first place it is not always easy to determine the fact that "a very limited amount of tuberculosis" is present, "that is latent or arrested," as Biggs states it, from any evidence we can obtain from the physical examination. Equally skilled diagnosticians may differ as to the existence of modified respiration or deficient resonance. In the second place it is a debatable question whether all cases of "a very limited amount of tuberculosis that is latent or arrested is almost certain to break down under the physical strain of military training and army life,"—to quote Biggs again. Some will and some will not, in my opinion, just as some will and some will not of those whose amount of tuberculosis is not much more than that of their childhood infection and which no human skill can detect. Herein come the judgment and experience of the examiner to determine, so far as may be, which of the two contingencies is most likely to happen and to act accordingly. The family and previous history, the length of time the disease has been arrested, if it has ever been active, the present physical condition as to weight, strength, muscular development and nutrition, the way the soldier has performed his military duties up to the time of his examination,—are all more vital points in making the decision, it seems to me, than the physical findings alone. An old "very limited" fibroid condition of many years' standing which has never shown any symptoms of breaking down under the ordinary conditions of civil life, or has in no way affected the general health, has a more than equal chance, I believe, of remaining firm under the extraordinary conditions of military life, and would appear to be a justifiable risk. It is a significant fact which I learned from Dr. Miller, who has been studying the tuberculosis problem in France, that the French think that mild cases of tuberculosis, whatever they mean by "mild cases," are improved in the trenches and in war activities—an opinion supposedly based on observation and quite contrary to that of Dr. Biggs quoted above.

On the other hand, a dubious family and personal history with a tendency to lowered resistance under slight or moderate provocation, indifferent assimilation, unsatisfactory development, and failure to develop vigorous health under training, with the same amount of latent trouble, will indubitably break down under the continued strain of army life and would be an unjustifiable risk. To treat both cases alike because they both show the same physical signs or the same *x*-ray picture, and to reject both, would seem to be poor judgment on the part of the examiner and defraud the Army of some good men who would in all probability go through the ordeal without developing active disease. Of course it is obvious that the consequences of a wrong decision in these latent, arrested no-symptom cases both to the Army and to the individual are more serious than in civil life. With the soldier it is the question of the continuance or abandonment of his occupation,—that is, of his military life—while with the civilian no such decision ordinarily has to be made, or, if it does, such serious possibilities are not involved as in the former case.

It is generally believed, and the evidence at hand seems to confirm this belief, that almost every adult has acquired some time during his childhood a tuberculous infection, which has caused more or less deposition of tubercle in his glands or lungs. When such latent tuberculous infiltration is extensive enough to give definite physical signs, but with no symptoms, we are told that such latent disease

should disqualify a man from active service. On the assumption, to quote Biggs once more, that this inactive process "will almost certainly become active" —how do we know that the lesser infiltration or the deeply buried focus which we do not or cannot discover will not break down as well as the discoverable amount? Or that the discoverable amount will not remain latent and inactive under military life and conditions as well as the undiscoverable amount? We all know that a certain unknown number of men who are passed as without discernible signs of tuberculosis will later develop the disease in the Army; in this case it is the undiscoverable or undiscovered amount which has become active. It would be an interesting and instructive observation if some of these latent symptomless cases which could be discovered by physical signs or the *x*-ray should be permitted to enter the Army, and compare the results with those in whom no discoverable signs of latent tuberculosis were present. In other words how many greater infiltrations would break down and how many lesser ones.

After all, the "conclusion of the whole matter" in our present state of knowledge in regard to eliminating tuberculosis from the Army is to reject all obviously active progressive cases, and, secondly, to reject or refer to the non-combatant force all latent, inactive, arrested cases which one's experience and judgment decide would probably break down under active military life. When all this is done it is a fairly debatable question just how much it will lessen the incidence and development of tuberculosis in the Army, for the real test of the soldier's ability to go through the strain of military service without developing the tuberculous infection or latent focus he has, or may have, into activity is not whether or not he has some discoverable lesion, the "very limited amount" of Biggs, but it is dependent upon that illusive and unknown cellular response to infection and to his hidden lesion under varying conditions of life which we call *resistance* and whether or not the barriers which shut in the tubercle will withstand the drive. It is Hindenburg *versus* the Allies.

Do what we will to exclude tuberculosis from the Army, it is, of course, inevitable, as I have said, that a certain percentage of the men while in France will develop the disease and in consequence will have to be removed from the active force and placed under treatment. Already government sanatoria have been planned, or existing ones taken over, for the care and treatment of such invalided soldiers. Why not treat the curable cases in Europe where they are? In some favorable climatic regions of France? Such a plan would enable the men to be placed under treatment almost at once, and would avoid the long and weary journey overseas with its incident risks. We all recognize the capital importance of beginning treatment at the earliest possible moment after active disease is discovered. Moreover, the expense of the long transportation would be saved and accommodations and treatment abroad would probably be not more expensive than in this country, if as such. Furthermore, it is the desire of the Surgeon General's department, as reported by Dr. Pattison[2], that the returned tuberculous soldiers should give themselves entirely to the business of getting well, and consequently they should not be placed in sanatoria close to their homes on account of the distractions of visiting friends and relatives. This objection would, of course, be obviated if the treatment was conducted abroad. Of course, some men would prefer to return to America for treatment on account of personal considerations, but others, I believe, would be glad to embrace the exceptional opportunities that could be offered abroad. In France there are good climatic conditions for the curative treatment of pulmonary tuberculosis, and accommodations could be found in existing sanatoria and the various health resorts—now empty of guests—in the French Alps and Pyrenees, in the Riviera, at Pau, Cauterets, and many other places. They are but a comparatively few hours distant from the Western front, and the American soldier unfortunate enough to develop tuberculosis could be under treatment in a favorable climate almost at once after the discovery of his disease. I am unaware that such a plan has been proposed, but it seems to me a reasonable one to be considered.

AN ANALYSIS OF THE WEAK FOOT WITH REFERENCE TO PRECISION IN THE USE OF DESCRIPTIVE TERMS IN TEACHING.

By ROYAL WHITMAN, M.D.,

NEW YORK.

In 1917, 2,736 new patients applied for the treatment of weak feet at the Hospital for Ruptured and Crippled and it has been estimated that from 30 to 40 per cent. of those examined by the exemption boards during that year presented either potential or actual disability of this character. Numerically, therefore, and particularly from the military standpoint, the weak foot is the most important of the orthopedic affections.

Many years ago I presented the proposition which I have since upheld, that the most direct of the predisposing causes of the so-called flat foot is a posture that simulates the deformity, which may be defined as a persistent attitude of abduction. In this attitude, the mechanism is functionally out of gear and is subjected to abnormal strain when in active use. Treatment, therefore, whether preventive, curative or palliative, depends for its effectiveness on the restoration as far as may be of the normal mechanical relations.

This proposition, once novel, is now, I think, generally accepted by orthopedic surgeons, but it is not understood by the profession at large as represented by the men sent to me for instruction in military orthopedics, nor is it clearly presented in the literature of the subject.

The first essential of effective demonstration is precision in the use of descriptive terms and since there is an evident confusion on this point as it relates to the weak foot, one may with advantage

analyze the attitude, that when persistent becomes deformity, before deciding on the term that best describes it.

When normal feet are placed side by side with the heels and toes apposed, an interval persists between them, caused by the slight outward curve of their inner borders. In this position the line of strain transmitted from the muscles of the calf passes through the center of the leg to the neighborhood of the second and third toes, and the weight is properly balanced on the foot.

The most important indication of the potential or actual weak foot is a bulging inward, so that the two feet when placed side by side are in contact throughout their entire extent or, if the bulging is more pronounced, it is impossible to appose the heels and toes simultaneously. If the heels are in contact, the toes diverge or vice versa.

The bulging is caused by the inward and downward rotation of the astragalus upon the os calcis, rolling the foot over toward the inner side, depressing relatively the arch, and, since the leg, resting on the astragalus must rotate inward with it, the line of strain is deflected from the center of the fore foot and falls over its inner border. Thus the most noticeable of the physical signs of the weak foot on inspection is the inward bulging; the most significant is the change in the relation of the power to the fulcrum; the least important, the incidental depression of the arch.

This attitude, characteristic of the weak foot, may be described by any one of three synonymous terms:

1. Eversion.
2. Abduction.
3. Pronation.

Eversion, to turn over, refers primarily to the relation of the sole to the base in which its inner border is depressed and the outer elevated.

Abduction refers primarily to the divergence outward of the foot in its relation to the leg.

Pronation, analagous to the movement of the fore arm that turns the hand over, refers primarily to the inward rotation of the leg and the effect upon the foot.

If the foot is well arched and compact, the outward deviation from the middle line of the leg will be more apparent than the inward bulging. If its structure is relaxed, the bulging and depression of the arch will be more noticeable. They are, however, component parts of a tilting of the foot as a whole beneath the astragalus and the terms are for all practical purposes synonymous because the movements are circumscribed by the same joints. One cannot abduct without everting, nor pronate without abducting. If authority is desired for a statement that can be so easily demonstrated, Rudolph Fick* may be quoted. Many, he says, in describing the outward and inward tilting of the foot, use abduction and adduction. The surgeons use pronation and supination, and the English, eversion and inversion.

Of these terms, eversion has the disadvantage that its meaning is sometimes confused with outward rotation of the limb, and since it refers primarily to the sole it is difficult to demonstrate when the foot bears weight.

Pronation is a German term, never used by English anatomists, and is from the standpoint of analogy, very difficult to demonstrate because the arrangement of the arm and leg bones is entirely different. Furthermore pronation signifies activity while the characteristic of the weak foot is passivity.

Abduction is, it seems to me, preferable to either because the change in the line of strain is most noticeable when the foot bears weight and the mechanical disadvantage of such an attitude for active use is very apparent.

I have found this preliminary exposition the more necessary because the meaning of the descriptive terms is usually confused by the student and often by writers on the subject. For example, in one of the authoritative Manuals of Orthopedics, eversion is used to indicate divergence of the feet caused by outward rotation of the limbs, whereas in true eversion of the foot the limb is relatively rotated inward and even the everted foot may be habitually turned inward, as is illustrated by the symptomatic pigeon-toed gait which is a common symptom of the weak foot in childhood.

Abduction is described as a free lateral movement in the medio-tarsal joint, where its range is so limited as to be negligible, as may be demonstrated by fixing the heel or by noting the contour of the external border of the foot in the contrasting attitudes of abduction and aduction.

Finally the weak foot is said to be a combination of pronation and abduction which, however accurate, is hardly intelligible from the foregoing descriptions.

The consideration of the weak foot from the standpoint of functional mechanics clears away much of the obscurity about what is in reality a simple subject. For example, a foot habitually used at a mechanical disadvantage is predisposed to injury and since the primary symptoms of all weak feet are those of strain, the immediate disability has no proportionate relation to the degree of deformity. In fact, the well-formed foot subjected to persistent strain provides the most favorable opportunity for progressive and irremediable disability, since stability (flatness) cannot be acquired without great lateral distortion and consequent disorganization of its structure. Whereas, the actual flat foot, an individual or racial pecularity, or one that is acquired in early life, may be perfectly competent because stability does not require excessive lateral distortion of its component joints.

From this standpoint one may estimate fairly the prospective ability of the weak footed recruit.

The most favorable type is the well-formed foot in which the normal relations can be voluntarily restored.

The next is the actual flat foot with but little lateral distortion.

The last is that, in which the changes of structure in accommodation to habitual deformity have advanced so far that the normal relations cannot be restored either voluntarily or by manipulation.

The treatment of the weak foot follows the same principle. The first indication is to relieve the symptoms of strain and injury, but the final purpose is to assure the normal relation between the power and the fulcrum, as the essential preliminary for the restoration of muscular power and balance

*Anatomie der Gelenke; Spezielle Mechanik.

upon which permanent cure depends. It is this purpose and the means employed to accomplish it that distinguish reconstructive treatment from the common routine, which is practically limited to the relief of the immediate symptoms.

FEEDING IN MARASMUS.

By MARK S. REUBEN, M.D.,

NEW YORK,

ASSISTANT IN DISEASES OF CHILDREN, COLUMBIA UNIVERSITY; ADJUNCT VISITING PEDIATRIST, BETH ISRAEL HOSPITAL.

For centuries, men wasted useful lives in a futile attempt to find the elixir of perpetual youth and life. For many decades physicians have vainly tried to discover a feeding formula on which all infants would thrive. From time immemorial men have had visions which built bridges from dreamland to truth. Sir Launfal, in his search of the Holy Grail, traveled over land and sea without avail; he finally returned, an old man, and found it in the domain of his own castle. The essence of truth which this parable contains is applicable to every sphere of life; and so it has been in the feeding of infants. A page could easily be filled with the names of men who have devised formulas and milk mixtures for the feeding of healthy and atrophic infants; these new mixtures have had their entrances and their exits; they always attract attention, but seldom survive the test of time. The realization of the fact that in the proper modification of Grade A bottled milk, with the addition of suitable carbohydrates, we have found the object of our search, may sound prosaic, but it is true.

Infants need not die of marasmus. With the means we possess to combat it, infantile marasmus should be a disease of the past. The means and the armamentaria which we possess are the broader and the more rational application of knowledge we already have; no new mixtures, no new facts are necessary.

From an experience with over 1,000 atrophic infants we are thoroughly convinced that if an atrophic infant can be saved it can be saved by the use of properly modified, clean, bottled milk, with the addition of suitable carbohydrates; and if it cannot be so saved, then no manufactured food will save it. If the general practitioner would only realize how quickly atrophic infants respond to simple mixtures, and that the same principles laid down for healthy infants are applicable to marasmic infants, it is certain that the rate of mortality from this cause would be lowered tremendously.

In two previous papers we have discussed the fundamental principles of the art and the science of breast and artificial feeding of healthy infants. In this paper it is our aim to discuss the fundamental differences between healthy and atrophic infants, in the chemical composition of their bodies, and in their nutritional requirements.

Marasmus is not a disease entity; it is a condition. It simply implies that the infant is in a wasted state, without suggesting the cause of this wasting. It may be due to various causes, such as congenital debility, constitutional disease, institutional life, neglect, unhygienic surroundings, and, most frequently, it is a result of chronic nutritional disturbances.

In undertaking the treatment of a case of marasmus due to a nutritional disturbance we must always be sure that the other causative factors are excluded; we must be sure that the case is a feeding case only; it is evident how fruitless our efforts will be if we do not recognize and do not treat an underlying luetic infection, which may be the cause of the malnutrition, or if other causative factors are not corrected. Very often, multiple causes are operative in the same case, all of which must be corrected if success be desired.

When we are satisfied that the malnutrition is due to a nutritional disturbance we must go a step farther and determine the exact nature of the nutritional disturbance. The term nutritional disturbance also is a generic one, which does not specify the exact nature of the disturbance; it is only within the last 10 years that we have learned to differentiate the various factors which may be responsible for the marasmus. The various causes of malnutrition are given below. In every case we must determine all the causes which are responsible. In no two cases shall we find the same exciting causes, and therefore in no two cases will the treatment be the same.

Etiology of Nutritional Disturbances.

1. Constitutional inferiority.
   - A. Hereditary causes; congenital debility; lues; tuberculosis
   - B. Congenital causes: congenital heart; pyloric stenosis; Hirschsprung's disease; atelectasis; myatonia; harelip; cleft palate; adenoids.
   - C. Acquired causes: lues; tuberculosis.
   - D. Due to presence of diathesis: exudative; neuropathic; spasmophilic; anemic; hemophilic; etc.

2. Alimentary causes.
   - A. Formula proper.
     - (a) Quantity of food improper: overfeeding; underfeeding.
     - (b) Improper technique.
       - Too much or too little at a feeding.
       - Food given too fast or too slowly.
       - Food given too frequently or too infrequently.
       - Too many or too few feedings.
       - Food improperly administered.
       - Food improperly prepared.
     - (c) Poor milk—fat or solids too low.
   - B. Formula improper: Fats too high or too low; sugars too high or too low; too much flour; proteins too high or too low; salts too high or too low; water too much or too little; improper relations of elements to one another; insufficient vitamine content.
   - C. Improper and unsuitable breast milk.

3. Disturbances of motility and secretions of gastrointestinal tract.
   - A. Delayed motility: Fat too high in formula; Pyloric stenosis; Hirschsprung's disease.
   - B. Increased motility.
   - C. Deficient secretion of HCl; of lipase.

4. Intoxications.
   - A. Toxin introduced from outside.
     - (a) In milk: Boric acid; salicylic acid; Benzoic acid, etc.
     - (b) In breast milk, Hg, morphine, I, etc.
     - (c) Preformed in milk by bacteria.
     - (d) From nipples, pacifiers, toys.
   - B. Toxins elaborated in the gastrointestinal tract: By bacteria and intestinal juices from milk, the juices, and from bacterial bodies.
   - C. Toxins excreted in the intestinal tract—elaborated elsewhere

5. Infections.
   - A. Enteral—typhoid; dysentery; cholera, etc.
   - B. Parenteral—pneumonia; influenza; diphtheria, etc.
   - C. Due to abnormal virulence of normal flora (*Bacillus coli*, enterococcus).

6. Improper hygiene.
   - A. Neglect.
   - B. Insufficient or improper bathing, clothing, exercise
   - C. Overheating, chilling.
   - D. Overcrowding.
   - E. Lack of mothering, etc.

The most common cause of marasmus is improper alimentation. Intolerance for milk as a whole, or for any of its elements, is the least common cause; for every case of malnutrition due to intolerance there are nine due to over or underfeeding, irregular feeding, improper technique or method of preparation. Of the intolerances, that for fat is most frequent (70 per cent.), for sugar less frequent (20 per cent.), and for protein least frequent (10

per cent.). In this paper only those cases of marasmus due to improper alimentation will be considered.

Chemical Composition of Atrophic Infants.—From the earliest fetal development to the birth of the full-term infant, the human embryo becomes poorer in water and richer in ash; thus a fetus at 6 weeks is composed of 97.54 per cent. water and 0.001 per cent. ash; at 6 months, 89.20 per cent. water and 1.94 per cent. ash; at birth, 71.8 per cent. water and 2.7 per cent. ash. The same process of dehydration and enrichment in salts continues to adolescence and old age. The differences in the chemical composition of the adult and the infant are shown in the following table:

	Water, per Cent.	Fat, per Cent.	Carbohydrate, per Cent.	Protein, per Cent.	Ash, per Cent.
Adult	60.8	15 0	1 0	18 0	6 0
Newborn infant	71 8	12 3	. . .	11 7	2.7

Numerous chemical analyses of infants who had died of marasmus have shown that atrophic infants do not differ from normal infants in chemical composition to any appreciable extent; the only noticeable difference is the reduction of fat in the atrophic infants. The percentage composition in regard to protein, salts, and water is nearly the same as in normal infants (see table). It seems that the chemical composition of the body does not become altered in chronic malnutrition, and that it is impossible to effect such changes through the alimentary tract. In marasmus the infant's loss of weight is at first due to loss of stored fat, and then all elements seem to be equally involved. An atrophic infant weighs less than a normal infant of the same age, but the chemical composition of the normal infant is maintained. The impulse for growth in infants is so great that they continue to grow (not to the same extent as normal infants) even when they do not gain or lose in weight.

100 Gm. Ash Contains

	Water	Fat	Nitrogen	Ash	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	Cl
Newborn infant	71.8	12.3	2.26	2.7	7.06	7.67	38 08	1.43	0 83	37 66	6.61
Atrophic infant	79.9	1 45	2 32	2.73	7.2	7.7	38 1	1.2	1.2	38 7	6.1

Fat Indigestion.—The symptoms which must be considered in the different types of indigestion are the appetite, the vomiting, and the stools. In fat indigestion the appetite is poor; the infant does not finish its bottle, and is not hungry at the next regular feeding time; this is due to the fact that there is some residual food in the stomach from the previous feeding. The fats are the last element of milk to leave the stomach. When milk is introduced into an infant's empty stomach part of the milk enters the duodenum in the same form in which it was introduced (without any digestion). This explains why infants often take greater quantities at a feeding than their anatomic capacity would indicate. Then the whey of milk—salts and sugar—pass into the duodenum; the next to pass are the proteins; the last to leave the stomach are the fats. It is evident why the appetite in cases which receive too much fat is bad, and why the vomiting in fat indigestion takes place some time after the feeding has been administered. The vomitus usually consists of creamy, rancid-smelling, curdled milk. The stools are gray or white, and are greasy or shiny; the stools smell strongly of butyric acid; they usually contain soft curds. When the soaps predominate they are dry and hard and are clay-colored and oily; the reaction of these stools is acid, and the odor is rancid. The gray stool is usually due to an excess of neutral fat; the white or soap stool is due to an excess of fat in the form of soaps. There are three requisites for the formation of soap stools: (1) A moderate amount of fat; (2) considerable amounts of casein and calcium salts; (3) an absence of large amounts of carbohydrates in the food.

Sugar Indigestion.—In sugar indigestion, the vomiting usually takes place soon after feeding, and is often repeated a number of times between feedings. The vomitus consists of sour-smelling watery fluid; flatulence and colic are usually due to indigestion of the carbohydrates, but may also be due to indigestion of protein or fat. The most marked symptoms in carbohydrate indigestion are intestinal, whereas those of fat indigestion are usually gastric. The stools are loose, green, and scald the buttocks; the odor is that of acetic acid or lactic acid. In severe cases, fever, glycosuria, and signs of intoxication are present; both sugar and starch may be present in the stool.

Protein Indigestion.—The vomiting in protein indigestion usually takes place some time after feeding, and the vomitus is cheesy, and consists of large, tough curds. The stools are loose, brownish, alkaline, and of putrefactive or fecal odor; very often they contain considerable amounts of mucus and hard or protein curds. It is the least common form of indigestion. The reaction of the artificially fed infant's stool is alkaline; that of the breast-fed infant is acid; the reaction depends on whether the nitrogen free elements (carbohydrates) or the protein predominate in the mixture; if the former is found in excess the reaction is acid; if the latter, it is alkaline. Thus an acid stool which scalds the buttocks may be changed into an alkaline stool by increasing the proteins and fats and by diminishing the carbohydrates; an alkaline stool may be changed into an acid stool by increasing the carbohydrates. Stools which scald the buttocks are usually acid. The carbohydrates are the laxative element of milk; regardless of which sugar is used, if a sufficient amount is administered, looseness of the bowels will be produced. The proteins are the constipating element of milk; this is brought about by the alkaline intestinal secretion which they call forth and on account of the putrefaction they undergo; the fats *per se* have no effect on the bowels; their effect depends on the amount administered; small amounts are constipating, large amounts are laxative. Their effect on the bowel movements is also dependent on the presence or absence of other elements of milk in the mixture. Thus, a high fat in the presence of a high protein content and a low carbohydrate and low salt content has a constipating effect; but in the presence of low protein and high carbohydrate content it has a laxative effect.

Curds make their appearance in the stool both

in fat and protein indigestion. The protein or casein curds are bigger, bean-shaped, hard, tough, and are white or yellow in color; the fat curds are smaller, softer, more easily broken down, and are of yellow-green color. The total loss of food in fuel value in the curds is, in the great majority of cases, very slight. The hard curds are derived from the casein, and usually disappear when the milk is boiled; the soft curds are derived from the fat of the food.

Mode of Onset.—The onset of the symptoms in fat indigestion is usually slow or subacute; only when the amount of fat in the milk mixture is very high is the onset sudden. In the mild cases there may be no symptoms present for a number of weeks, and they only make their appearance when the fat in the milk mixture is increased. Of all the different types of indigestion, that of fat is most apt to run a latent course at the beginning. In sugar indigestion the onset is subacute or sudden; in severe cases it may be fulminating. The symptoms are always manifest, even at the onset. This type of indigestion never runs a latent course. The symptoms of protein indigestion are the mildest of all the forms of indigestion, and are usually slow in development.

The appetite is always poor in fat indigestion; even when there are no other symptoms present; it is the premonitory sign of this type of indigestion, and unless heeded it means "trouble ahead." In sugar indigestion the appetite is good, except in severe cases with high fever; it is but slightly affected in protein indigestion.

The weight, in fat indigestion, may not be affected at the onset; in fact, for a time such infants may even be gaining slowly in weight. Stationary weight, in cases which receive sufficient calories in the food, should always lead one to suspect the presence of a mild type of fat indigestion. Big losses in weight in this type of case are only noted when the limit of tolerance for fat is overreached, and is usually associated with "fat diarrhea." In sugar indigestion, the weight depends on the number of stools which the infant passes and on the amount of water the stools contain. Very often, infants continue to gain in weight in spite of the presence of four to five loose, watery stools a day; however, in severe cases, with many watery stools, the loss in weight may amount to two to three pounds in one week; this is usually due to the fact that infants overfed with carbohydrates have their water in loose combination, which, in the presence of the slightest digestive disturbance is quickly lost. One should always look for edema in cases which receive a high percentage of carbohydrates and show marked gain in weight. In protein indigestion the weight is but slightly affected. The temperature, in cases with fat indigestion, shows at first more than normal oscillations; later the temperature has a tendency to become subnormal; in cases in which there is fat diarrhea it is apt to be elevated one or two degrees. In sugar indigestion the temperature is slightly elevated at first, and in severe cases may be as high as 105° F. In protein indigestion the temperature is not elevated except in cases which receive more than 6 per cent. protein in their food.

Metabolism.—Even in severe cases of atrophy, due to fat indigestion, the metabolism of the proteins is normal. In mild cases the absorption of fat is but slightly decreased—85 per cent. (normal, 95 to 98 per cent. absorbed); in normal stool, the calcium and the magnesium soaps constitute about 18 per cent. of the fat excreted in the stool; in mild cases of fat indigestion they may constitute 50 per cent. of the fat in the stool; the binding power of the calcium is so great, however, that this does not necessarily mean that there will be a negative balance of salts, but suggests that some of the calcium which would be excreted as calcium phosphate is now excreted in combination with fatty acids. In severe cases there is a loss of sodium and potassium salts in the stools, and this leads to increased excretion of ammonia in the urine, 15 to 20 per cent. (normally, ammonia forms 8 to 10 per cent. of the nitrogen in the urine). This is due to the fact that ammonia is called upon to neutralize the acids liberated by the withdrawal of the sodium and potassium bases.

In severe cases of marasmus due to fat indigestion the nitrogen retention is diminished, and there may be a negative balance; this is not due to deficient absorption, but to a loss of nitrogen from the disintegration of cellular tissue, as these infants excrete more nitrogen than they take in. When fat diarrhea is present the absorption of fat is very poor (25 to 50 per cent.), and the insoluble soaps of calcium and magnesium diminish in amount. Hess has shown a deficiency of lipase in these cases, and it is possible that part of the loss of fat is due to this cause. The tolerance for sugars in many of these cases is also diminished. The salt metabolism suffers most in these cases; there may be a negative balance. The loss of alkali bases leads to increased acidity of body fluids, and this in turn leads to increased ammonia excretion in the urine (15 to 20 per cent.).

In sugar indigestion the disturbances in the metabolism are due to the increased peristalsis and the abnormal secretion of the intestinal juices. In very loose stools there is a great loss of fat; the loss of fat runs parallel with that of the water; the greater the water loss the greater the loss of fat. In very loose stools there are hardly any soaps found at all (about 8 per cent.); most of the fat is in the form of neutral fat (65 per cent.) and fatty acids (27 per cent.). The amount of protein lost is about twice as great as in normal stools, but the relation of the nitrogen to the total residue is normal; most of the nitrogen excreted is derived from the intestinal secretions and not from the food. The actual amount of calcium in the loose stool is nearly the same as in the normal stool; the quantity of Na and K is very much increased. The residue (cellulose of bacterial origin) is very much increased in very loose stools.

The urine of infants overfed with flour shows no trace of chlorine; there is also a deficient salt content in the blood serum; the blood is hydremic; in the liver there is a deposition of salts and water; on the whole, the findings show an impoverishment of salts and an accumulation of water in the system. As the salts are not present, the water must be retained in a colloidal state.

In severe forms of sugar indigestion associated with acidosis due to retention of acid products, the

disturbances in metabolism are very marked. The nitrogen in the feces is much increased, due to the larger amounts of feces passed; the relative per cent. of nitrogen in the feces is not changed; the nitrogen in the urine is also increased, due to disintegration of cellular tissue. These infants seem to have lost the power to reduce the amino acids to urea, which is probably due to an insufficiency of the liver. The ammonia excretion is very much increased—40 to 50 per cent. of the nitrogen in the urine.

The fat resorption is diminished to 50 per cent. This is mostly due to increased peristalsis. Mellituria in these cases is due to disturbed carbohydrate metabolism, and is usually associated with hyperglycemia; the sugar is of alimentary origin, and the sugar which is introduced into the food is the one which is excreted into the urine. Glycosuria in these cases takes place long before the limit of tolerance for the sugar is reached. There is a great loss of water from the body in these cases, with severe diarrhea, and this leads to dehydration of the blood; and there is a corresponding increase in its viscosity. During the severe stages there is a great loss of salts, which can only be explained by the disintegration of cellular tissue. Sodium, potassium, and chlorine are lost in great amounts; only calcium and phosphoric acid are retained; the negative balance is due to increased excretion of sodium, potassium and chlorine in the feces; the bases are found in greater quantity than needed for the binding of the fatty acids, so that their increased excretion is probably due to increased peristalsis.

Clinical Findings.—In the early stages of fat indigestion the infant may appear well nourished, but in spite of sufficient calories in the food the infant does not gain in weight. For a time, anorexia is the only symptom; when the food is increased, gastric and intestinal symptoms make their appearance; general symptoms (pallor, diminished muscular tone, restlessness, disturbed sleep) soon make their appearance. If the fat in the food is not reduced, or if it is increased, acute symptoms supervene, and the infant may lose a pound in a few days; gradually they lose more and more in weight, until the complete picture of marasmus becomes manifest. The emaciation becomes extreme, the face looks senile and pale, the respiration is irregular and the expiration is prolonged, the pulse is small and slow, the temperature is subnormal, the tolerance for food and the resistance to infection are very much diminished; any erroneous change in diet may lead to a "weight crisis." These infants respond with very severe symptoms when subjected to starvation, and may suffer from collapse. On account of their lowered resistance to infection they are subject to influenza, bronchitis, etc., and very often a slight infection is the immediate cause of death. On account of their low resistance many of these infants are afflicted with various skin diseases (intertrigo, eczema, furunculosis).

The symptoms of sugar indigestion may appear in a previously healthy infant or in one suffering from fat indigestion; the weight is stationary, or there is slight loss of weight; when the stools are not too numerous there may be gain in weight for a time; slight fever is usually present; vomiting and diarrhea soon make their appearance; tympanites, increased peristalsis, and gas formation are prominent symptoms. In mild cases, if the symptoms are allowed to persist for any length of time, and the exciting cause is not corrected, the clinical picture of marasmus slowly but surely develops.

Infants who receive an almost exclusively flour diet are prone to develop a chronic nutritional disturbance which differs from overfeeding with sugars, and which usually leads to marasmus; this is particularly apt to happen in very young infants. The symptoms which these infants present may be of two different varieties: (1) The atrophic, which do not differ from other types of marasmus; (2) the hydremic. In this type, the emaciation is partly obscured by the retention and the accumulation of water in the subcutaneous tissues and in the tissues. Thus, in later stages edema is a prominent symptom. The face is pale and swollen; the eyes are puffy; less marked edema is present in the extremities; the urine is negative. The resistance to infection is very much diminished; any slight infection may prove fatal; the slightest disturbance causes great loss in weight. In both these forms there is often found marked hypertonicity of the musculature; often opisthotonus is also present. These infants are apt to develop tetany, and usually show other signs of spasmophilia. The stools in these cases may be of normal appearance; at times they have diarrhea; undigested starch is usually found in the stools.

When the diarrhea of carbohydrate indigestion becomes very severe, and when there is superimposed upon it an intoxication due to retention of acid inorganic salts, due to insufficiency of the kidneys, the whole clinical picture changes very quickly, and the symptoms of acidosis make their appearance. Hyperpnea is the chief symptom. The mental symptoms become marked; coma and unconsciousness are frequently present; the face is pinched; the eyes and cheeks sunken; the color is ashy gray, but no cyanosis is present; great loss in weight takes place; the fontanelle is depressed; the temperature is elevated, and there may be hyperexia (105° to 107° F.); vomiting, and especially diarrhea, are very marked; the breathing is toxic and deep; the pulse is flickering; the urine is diminished; and there may be complete anuria; albuminuria, and glycosuria of alimentary origin, are usually present; acetone breath is at times marked; at times only mere traces of acetone are found in the blood (in excess of normal amounts); no abnormal organic acids are found in the urine; but there is an increase of acid phosphates in the blood, due to insufficient excretion by the kidneys.

Differential Diagnosis.—The differential diagnosis is not always a simple matter. Extreme cases of acidosis, atrophy, or simple cases of fat indigestion, are easily diagnosed; the etiology is at times obscure; thus, acidosis and intoxication may be due to excessive fermentation and intoxication with bacterial products; it may also be due to excessive fat feeding (with diarrhea), or to severe intestinal infection, insufficiency of the kidneys, with diarrhea, and other causes. Atrophy, or marasmus, may be due to inanition, overfeeding, chronic fat indigestion, chronic sugar indigestion, secondary to

some constitutional disease or to some systemic or intestinal infection; it may also be due to improper hygiene and neglect. A careful history is therefore important. Of two infants, with soap stools, emaciation and stationary weight, one may improve on a fat-poor and carbohydrate-rich diet and another may develop diarrhea and lose weight; of two infants with marasmus, one may improve on large amounts of whole milk, and the other may lose in weight and die. Of two cases with loose stools, one may improve on starvation and reduced diet, the other may go into collapse, lose weight, and the diarrhea become aggravated.

One must be very careful not to misinterpret the findings in the stools. The examination of the stool may give valuable information, but undue importance should not be attached to them; slightly dyspeptic stools may accompany very severe as well as very mild cases, and, on the contrary, frequent diarrheal stools, with much mucus, may be present in mild cases as well as in fatal cases. When judging the nature or the severity of a nutritional disturbance, the findings of the stools must always be considered in conjunction with other symptoms. One must especially be careful not to misinterpret the findings in loose stools; in cases with increased peristalsis the food residue depends on the composition of the food introduced.

The history may clear up the etiology. A complete history of all the foods the infant had received from birth, and how he reacted to each, should be ascertained; every food formula should be reduced to calories and percentages, for it is only in this way that an accurate idea can be obtained whether the infant receives too much or too little food. It is only by carrying out this procedure, and by considering the findings in conjunction with the weight and age of the infant, that definite information can be obtained. A knowledge of all the diseases which the infant had suffered from birth is also important, because the nutritional disturbance may be secondary to some constitutional disease. Very often, in cases of fat indigestion, we obtain a previous history of overfeeding with carbohydrates; and on the contrary, in a small number of cases of sugar indigestion we obtain a history of overfeeding with fat. Tolerance and intolerance are relative terms, and the above statement may only mean that in those cases even small amounts of fat or sugar may produce symptoms of indigestion in susceptible infants. In severe cases of sugar indigestion, with numerous loose stools, one must always expect considerable fat indigestion, because the fat loss runs parallel with the water loss.

"General Principles."—The feeding of atrophic infants is simple, and can be made successful in the great majority of cases if one keeps in mind the underlying fundamental principles. These principles are few, clear-cut, definite, of almost mathematical exactness; disobedience of these rules leads invariably to ultimate failure. One can attain a successful result in the great majority of these cases by adhering to these principles. Attention to the smallest details is the key to success. The principles, which should guide us in the feeding of atrophic infants are:

1. A complete history and a complete physical examination of the infant to determine the cause of the malnutrition are essential.

2. Our first aim should be to prescribe a food which will preserve life and correct existing gastrointestinal symptoms. The first step must be a period of reparation. When the symptoms have subsided we must prescribe a food which will produce a regular gain in weight and proper physical development.

3. We must not keep an infant for too long a period on a food which is not well balanced, but which must be given at the outset to correct existing conditions. If we do, we may save the infant from the Scylla of marasmus and strand it on the Charybdis of scurvy and rickets.

4. When the gastrointestinal symptoms have subsided we must prescribe a formula in which the element for which there is an intolerance is reduced to a minimum, and in which the other elements are correspondingly increased to supply the desired number of calories. As radical as the first change in formula should be, so conservative must all further changes be (*e. g.* an infant who had been receiving 6 per cent. fat in its milk mixture, and developed an intolerance for fat, should be put on a mixture containing only $\frac{1}{2}$ to 1 per cent. fat; and when it has adapted itself to this amount of fat the next formula should contain only from $\frac{3}{4}$ to $1\frac{1}{2}$ per cent. of fat).

5. The more an infant is underweight the greater is the caloric requirement. Whereas healthy infants require from 40 to 50 calories to the pound, very few marasmic infants will thrive unless they receive 50 to 65 calories to the pound. No atrophic infant should receive its full caloric requirement at the beginning of treatment. No more than 35 calories to the pound should be supplied in the first formula.

6. The more an infant is underweight the greater is the water need. The quantity to be given at a feeding to an atrophic infant should be less than the age but more than the weight would indicate. A healthy infant requires about 2 to $2\frac{1}{2}$ ounces of water per pound in the second six months, whereas an atrophic infant would require 3 to 4 ounces per pound under similar circumstances.

7. No infant, whether healthy or atrophic, should receive more than seven feedings in the 24 hours; the intervals between feedings should never be less than three hours; in cases where vomiting is a prominent symptom the intervals should be 3 to 4 hours.

8. Never change the formula without a definite reason; never change the formula before the infant has had an opportunity to adapt itself to it; too many premature changes are the cause of many failures in the management of atrophic infants. All increases in the strength of the food must be more cautious and more gradual than in healthy infants.

9. As atrophic infants have a tendency to have subnormal temperature, normal bodily heat must be maintained by the use of cotton jackets and external heat.

10. A normal condition of the skin must be maintained. Proper airing and bathing are indispensable adjuvants of ultimate success.

11. One must always remember that in the feed-

ing of atrophic as well as healthy infants temporary success may mean ultimate failure and temporary (apparent) failure may mean ultimate success. In healthy infants, an improperly balanced diet may cause temporary gain in weight, especially if the carbohydrates are high, and may ultimately lead to scurvy or rickets; and on the contrary, in atrophic infants, a temporary but proper food may not produce immediate gain in weight. but leads to a correction of gastrointestinal symptoms. In healthy infants our aim is to procure regular gain in weight and proper physical development; in atrophic infants, however, our first aim is to relieve symptoms, even if the weight remains stationary, or if there be temporary loss of weight.

12. Frequent and regular observation of the infants (three times a week) is essential.

Treatment.—It is only after we have determined the exact cause of the marasmus that we are in a position to feed the infant rationally and scientifically; the treatment varies with the cause. We must have definite knowledge whether the marasmus is due to improper technique, to over or underfeeding, or to an intolerance for one or more elements of milk. The treatment also varies with the presence or absence of gastrointestinal symptoms.

We deem it advisable to wash the stomach of every atrophic infant when it comes to us for the first time. It is surprising how much mucus and products of fermentation are at times removed through this procedure. We then order a tenth of a grain of calomel (for every month of the infant's age) and allow only plain boiled water until the next morning. Great caution must be exercised in the starving of atrophic infants; these infants cannot withstand starvation for more than from 12 to 24 hours, and not infrequently show marked signs and symptoms of collapse as the result of it.

Our next endeavor is to correct existing symptoms. In cases where vomiting is a prominent symptom the infant's stomach should be washed daily, the intervals between feedings should not be less than 3½ to 4 hours, and the mother should be told to put the infant in an upright position immediately after feeding and gently to pat it on the back to assist it in the expulsion of any swallowed air. The formula should not contain a high percentage of fat, because of all the elements of milk this is most apt to delay the emptying of the stomach.

Infants in whom there is a tendency to looseness of the bowels, and who have from 4 to 6 loose green stools, with curds and mucus, should be put on a mixture which is low in sugar and which has a moderate amount of fat and a high percentage of protein. Such a mixture is conducive to the formation of soap stools which are solid and formed. Soap stools *per se* are not to be sought, nor are they desirable, except as a means to an end—from loose to normal stools.

This mixture controls the diarrhea by checking fermentation and by favoring putrefaction; the proteins produce an alkaline reaction in the intestines, and thus check the process of fermentation. For the formation of soap stools there are three requisites: A moderate amount of fat, a considerable amount of casein and calcium salts, and an absence of large amounts of carbohydrate in the food. We have only recently learned of the protective influence of fat on the intestines in cases with loose stools; it becomes evident why skim milk is contraindicated in cases with diarrhea, for under the circumstances there are no fatty acids present to unite with the alkaline bases to form soaps (the fatty acids are derived from the decomposition of fat). An excessive amount of fat in the mixture, on the contrary, may not only fail to control the diarrhea, but may aggravate it by producing an excess of fatty acids over bases. As no infant will gain in weight on a mixture which is low in carbohydrates, the infant should not be kept on such a mixture any longer than is necessary to control the intestinal symptoms; as soon as the intestinal symptoms have been controlled, carbohydrates in the form of dextrin-maltose, or flour, should be gradually added. When the infant is able to take 5 or 6 per cent. carbohydrates it should be put on a whole-milk mixture or on a skim-milk mixture with a high percentage of carbohydrates (if the infant is very much underweight).

A mixture which is low in carbohydrates, and contains moderate amounts of fat and a high percentage of protein, can be made from a bottle of whole milk, as follows:

L. S. Milk—Low Sugar Milk.—Take a bottle of Grade A whole milk and shake it so that the cream and the remainder are thoroughly admixed. To half a quart of this milk add two junket tablets; allow it to stand for half an hour; then strain, and discard the whey (which contains the sugar, the salts, and the lactalbumin); the curd is rubbed through a fine sieve into the other half quart of milk; enough plain boiled water is added to make one quart. The whole mixture is now brought to a boil (to destroy any further action of the junket tablet), under constant stirring, and is ready for use. Add no sugar to this mixture. No infant should receive more than one quart of this mixture in the 24 hours.

Atrophic infants who present no gastrointestinal symptoms (there are very few such cases) should be put on mixtures made from properly diluted whole milk, or if they are very much underweight on skim milk with a high percentage of carbohydrates.

Atrophic infants who have an intolerance for one or more elements of milk must be put on mixtures which contain the element for which there is an intolerance reduced to a minimum, and which contain a high percentage of the other elements which are necessary to make up the caloric requirement. Thus, in cases of fat intolerance, we use skim milk, with a high percentage of carbohydrates; in sugar intolerance we may use top milk dilutions (with no addition of carbohydrates) or we may use the mixture described above, made from whole milk, in which part of the sugar of milk is removed; in protein intolerance the casein may be removed by the use of whey and the amount of casein in the milk formula may be gradually increased by adding more of the curd to the milk mixture; protein digestion may be facilitated by the use of alkalies (no protein digestion takes place in the stomach in an alkaline medium, we must add 25 to 50 per cent. lime water), by the use of cereal diluents

(casein is precipitated in much finer flocculi), by the use of sodium citrate (1½ grain of sodium citrate to every ounce of milk used—the milk does not curdle under these conditions), by boiling, peptonizing, or homogenizing of the milk. In most cases all that is necessary is to bring the milk to a boil and all the symptoms of protein indigestion usually disappear.

Uses of Skim Milk.—In 1909 a study was undertaken to determine the value of different kinds of milk (skim, whole, or top milk) as proper substitutes for breast milk, in cases in which the latter was not available. A large number of infants were fed on each kind of food and they were observed for from one to two years, the effects of each kind of milk on the development, the morbidity, and the mortality of the infants being carefully noted. The results of our studies have conclusively proved to us that in the use of proper dilutions of whole milk we have the best substitute for breast milk; we were equally convinced that skim milk, although not suitable as a permanent food for healthy infants, was of great value as a temporary food in all chronic cases of malnutrition, in which the infants presented no gastrointestinal symptoms and were very much underweight. Skim milk with a high percentage of carbohydrates produces a more rapid gain in weight than any other mixture known.

The advantages of this method of feeding are:

1. It eliminates or reduces to a minimum the fat of the milk, an element which is the most difficult to digest, one which most frequently causes indigestion, and one which requires for its proper digestion a greater expenditure of energy than any other element of milk.

2. It makes it possible to furnish a high percentage of carbohydrate in the mixture; the carbohydrates are the most easily assimilable elements of milk; they require a lesser expenditure of energy for their digestion than any other element of milk. When the fats in a mixture are low, a much higher percentage of carbohydrates can be given to advantage than when they are high; to a certain extent the fats and the carbohydrates are interchangeable; when the fat in a mixture is not above 1 per cent. as high as 10 to 15 per cent. of carbohydrates will often be tolerated for a number of weeks without the slightest sign of indigestion. The carbohydrates have the greatest influence on the weight; they also have the greatest laxative effect; and when given in excess they are apt to cause a retention of abnormal amounts of water with resultant edema, and glycosuria may be present. The appearance of vomiting and loose stools in an infant who receives a high percentage of carbohydrates should always lead to an immediate reduction of this element. If the early symptoms of vomiting and diarrhea are not heeded the complete picture of acidosis with hyperpnea, anuria, glycosuria, and coma may develop within 12 to 24 hours.

3. The protein, an element which but seldom causes any indigestion and an element which is essential for growth, is found in a high percentage in skim milk; as infants suffering with chronic malnutrition are undersized, the presence of a high percentage of protein offers material for tissue building. The presence of a high percentage of protein makes it also possible to prescribe such high percentages of carbohydrates, without the production of loose stools. When the proteins in a milk mixture are abundant they call forth an alkaline intestinal secretion and in this way counteract the tendency of the carbohydrates to produce fermentation. The proteins seem to exert a beneficial influence in other ways also; when an infant who receives a skim milk mixture with a high percentage of carbohydrates is put on a mixture containing the same number of calories, but the proteins are made lower, and either the fats or the carbohydrates are made correspondingly higher, there is no gain in weight for a number of weeks (under the circumstances the salts are also made lower and it is possible that the deficient gain in weight is due to decrease in salts).

4. The salts in this mixture are high, and are, therefore, helpful in the retention of water; the infants for whom this kind of mixture is indicated are usually atrophic and dehydrated; the retention of large amounts of water is therefore helpful and desirable and becomes deleterious when it is retained only extracellularly (*i.e* when it gives rise to edema).

5. A greater number of calories can be supplied to an infant in the form of skim milk with a high percentage of carbohydrates than in the form of whole or top milk. Any one who has fed a large number of infants can recall cases which for a time were gaining in weight, then stopped gaining, and when the food was strengthened they immediately began to lose in weight and developed gastrointestinal symptoms.

At times marantic infants die of starvation because not enough food can be supplied to them without producing a gastroenteritis. In these cases more calories per kilo can be supplied in the form of skimmed milk with a high percentage of carbohydrates than any other milk mixture without producing a gastroenteritis, and with resultant gain in weight. In a number of cases we have been able to prescribe from 75 to 85 calories to the pound, with resultant gain in weight and with continued benefit to the infant, and without the development of any digestive disturbances. The prescribing of the same number of calories in the form of whole or top milk invariably led to severe digestive disturbances.

Skim milk mixtures with a high percentage of carbohydrates are especially indicated in cases of (1) fat intolerance; (2) malnutrition due to underfeeding; (3) malnutrition following acute infectious diseases; (4) all cases of malnutrition without gastrointestinal symptoms; (5) weaning. (They are contraindicated in all cases of sugar and protein intolerance.) (6) They are also indicated in infants born prematurely and congenitally debile. The fat-splittig ferment is the only ferment which is found in deficient quantities in prematurely born infants, in marasmus, and in febrile conditions. All the other ferments are present at birth (including starch-splitting ferment) and their concentration in the intestinal tract is not affected in marasmus.

Technique.—1. We must first determine the kind of milk which is indicated in the particular case (whole, top, skim, or "curdled low sugar" milk).

2. The next step is to determine the quantity to be given at a feeding, the number of feedings in the 24 hours, and the total quantity in the 24 hours.

3. Calculate the caloric requirement of the infant; in the first food it is seldom advisable to furnish more than 30 to 35 calories to the pound. Slowly but steadily increase the strength of the formula until the full caloric requirement is covered and the infant begins to gain in weight.

4. Never change the formula without definite reason. In the first few days after the infant had been put on a new formula our policy must be one of watchful waiting; our first aim must always be to abate symptoms and to improve the general condition; when this is accomplished we must aim to produce regular and sufficient gain in weight and proper physical development.

5. The quantity at a feeding should be increased by half an ounce every two or three weeks; no infant under one year should receive more than 42 ounces in the 24 hours.

6. As atrophic infants are apt to be anemic they should receive other articles of food (fruit juices, cereals, vegetables, beef juice, yolk of egg) before they reach the normal weight for their age.

7. As the flours are less fermentable than the sugars they have a greater field of usefulness in infants in whom there is a tendency to looseness of the bowels than in healthy infants. Of the sugars the dextrin maltose preparations are the most useful in cases of atrophy, because they are least apt to produce looseness of the bowel and because they produce the greatest gain in weight. Lactose seems to be the most laxative of the sugars and should therefore not be used in cases where there is a tendency to looseness of the bowels. In healthy infants it is never advisable to raise the sugar above 7 per cent in the mixture; when the food must be strengthened it is always better to increase the milk (not above one quart) than to raise the carbohydrates above 7 per cent. In cases of fat intolerance it is sometimes necessary to raise the sugar to from 10 to 13 per cent.; in these cases part of the carbohydrate must be given in the form of flour, and more than one kind of sugar must be used in the same mixture. In this way we can prescribe a high percentage without developing an intolerance. No infant should be kept on a mixture containing over 10 per cent. of carbohydrates for any length of time, because such infants usually have a diminished resistance to infection, even though they may be above normal in weight.

8. In cases in which skim milk is ordered the first formula should not contain more than 1 per cent. fat; to obtain a 1 per cent. milk we must remove the upper 8 ounces; as all the fat that rises as cream does so in the top 8 ounces, the percentage of fat in the remainder of the milk is of uniform composition (1 per cent. fat); it is thus not possible to obtain a skimmed milk of less than 1 per cent. fat by the gravity method. When a fat-free milk is desired the fat must be removed by a centrifuge or separator. When the infant is adapted to take 1 per cent. fat we should then order 1½ per cent. fat in the mixture (a skim milk containing 1.5 per cent. fat is obtained by removing the upper 6 ounces; the lower 26 ounces contain about 1½ per cent. fat); and then we gradually skim less and less (one ounce at a time) until the infant takes whole milk. As the fat in the mixture is raised the sugar is proportionately lowered.

9. In cases in which top milk is indicated, we begin with a 10 per cent. milk. A 10 per cent. milk means that the fat in the milk is 10 per cent. The proteins, the sugars, and the salts, in top milk, whole milk, and skim milk are approximately the same (proteins 3.5 per cent., sugars 4.5 per cent., salts 0.75 per cent.); slightly less in top milk, except very rich cream, where they are reduced to two-thirds of the original quantities. To obtain a 10 per cent. milk we must use only the upper 16 ounces of the bottle. As the infant develops greater tolerance for carbohydrates, we decrease the fat in the mixture by using a 9 per cent. milk (obtained by using the upper 12 ounces) and correspondingly increasing the carbohydrates. As the infant's tolerance for sugars increases we decrease the fat in the mixture by successively using 8, 7, 6, 5, and 4 per cent. milk.

10. In cases in which the low sugar milk mixture above described (L. S. milk) is used we must keep the infants on this mixture until soap stools are obtained. As infants but seldom gain in weight on this mixture, on account of the low carbohydrate content, we must begin to add carbohydrates to the mixture (preferably flour or dextrin maltose sugar) very gradually; when the infant is able to take 5 to 6 per cent. of carbohydrates in this mixture to advantage it should then be put on a whole milk mixture or on a skim milk mixture with a high percentage of carbohydrates (if the infant is very much underweight).

*Orange juice, 2-3 ounces; between the first and second bottles.
†Beef juice, 2-3 ounces; in the afternoon.
‡One tablespoonful cereal: farina, rice, oatmeal, barley; boiled in a double boiler, for at least three hours, not to be strained, to be fed with a spoon.
§Three tablespoonfuls cereal.
**Vegetable soup; peas, beans, spinach, carrots, potato, to be boiled for three hours in a little water, strained through a fine sieve and to be fed with a spoon, a rounding tablespoonful at a feeding.

weight 7 pounds 2 ounces, breast fed for seven weeks, was then put on a mixture containing mixed milk 1 ounce, barley water 3 ounces, and granulated sugar one-half teaspoonful; this quantity was given every two hours, eight feedings in the twenty-four hours. The infant vomited from three to four times in the twenty-four hours, almost immediately after feeding, probably due to agitation and hunger contractions; the bowels were constipated. The infant came to our clinic at the age of forty-six weeks, weighing 10 pounds 6 ounces. In the first few weeks under treatment the infant did not gain in weight, because the full caloric requirement was not supplied. The general symptoms, however, almost entirely disappeared. As soon as the full caloric requirement was supplied the infant began to gain from 6 to 8 ounces every week. The vomiting subsided in the course of three weeks, and the bowels became regular and moved spontaneously.

CASE II.—*Marasmus Due to Fat Intolerance.*—L. M., birth weight 7 pounds 12 ounces, breast fed for four weeks; as the breast milk diminished the mother put the infant on condensed milk (two teaspoonfuls to 4 ounces of water); this was gradually increased in strength, so that at nineteen weeks the infant was taking four teaspoonfuls of condensed milk to 6 ounces of water every two hours. The infant vomited almost immediately after every feeding and the bowels were constipated. The mother consulted a physician, who put the bahy on the following formula: Top milk, 12 ounces (the upper 6 ounces of two bottles), 24 ounces of barley water, 2 ounces of lime water, and 1 ounce of milk sugar. There was marked aggravation of all the symptoms. The infant now began to vomit also between feedings and the bowels were very loose (seven to eight times a day). On this mixture the infant lost from 4 to 6 ounces every week. The infant came to our notice at the age of thirty weeks, weighing 8 pounds 4 ounces. In the first few weeks there was no gain in weight, because L. S. milk is low in sugar. As soon as the stools were controlled dextrin-maltose was added. Later the infant was put on a 1 per cent. milk, and one-half tablespoonful of granulated sugar and 1 ounce of dextrin-maltose were added. From this time there was regular gain in weight. The milk was skimmed less and less and the sugars were correspondingly lowered. At sixty-two weeks the infant was of normal weight and development.

CASE III.—*Marasmus Due to Sugar Intolerance.*—Grace Mc., birth weight 7 pounds 6 ounces, breast fed for four weeks; best weight while on the breast was 7 pounds 4 ounces. There was considerable vomiting about fifteen minutes after nursing and the infant had from six to eight loose green stools every day. It was then put by a physician on mixed feeding: mixed milk, 5 ounces; boiled water, 15 ounces; milk sugar, 1 ounce. Three ounces of this mixture were given every three hours immediately after nursing. The child continued to vomit and to have six to eight green stools with mucous and hard curds; the buttocks were excoriated. At eleven weeks she consulted another physician, who weaned the infant entirely and prescribed the following formula: 10 ounces of mixed milk, 11 ounces of boiled water, and 1 ounce of cane sugar. The vomiting and the loose stools continued. There was no gain in weight. Then the infant was brought to our notice, weighing 7 pounds 15 ounces at fifteen weeks. From the symptoms it was evident that this was a case of sugar intolerance, and the infant did very well on top milk mixtures without the addition of carbohydrates.

As soon as the infant was put on top milk the stools decreased in number and the infant began to gain in weight. The fat in the formula was gradually decreased and the sugar slowly but gradually was increased. At six months the infant was able to take 6 per cent. carbohydrates. (Ten per cent. milk is obtained by using only the upper 10 ounces of a quart; 9 per cent. milk, the upper 12 ounces; 8 per cent. milk, the upper 14 ounces; 7 per cent. milk, the upper 16 ounces; 6 per cent. milk, the upper 18 ounces; 5 per cent. milk, the upper 24 ounces, and 4 per cent. milk, the whole 32 ounces.)

316 WEST NINETY-FOURTH STREET.

THE RESULTS AND INTERPRETATION OF THE WASSERMANN TEST.*

BY CLARENCE A. JOHNSON, A.B., M.D.,

LOS ANGELES, CAL.

ATTENDING (FORMERLY RESIDENT) PATHOLOGIST TO LOS ANGELES COUNTY HOSPITAL.

IN this paper I shall give a preliminary report of the present status of the Wassermann test in diagnosis, and as a control in the treatment of syphilis, together with some of the things which I have found to be of practical value from my experience with over six thousand Wassermann tests which I performed personally at the Los Angeles County Hospital.

The Wassermann test has been given a thorough trial in all parts of the world with the result that the consensus of opinion is that, all in all, it is the most valuable aid that we possess in the diagnosis of syphilis. This test is the most delicate and persistent of all the symptoms of syphilis and one should not consider a patient cured of syphilis so long as the blood or spinal fluid reacts positively. If this reaction is persistently positive we are sure that there is present somewhere in the body, the living spirochete. This is further proved by the

*Presented before the Innominate Medical Club of Los Angeles, Cal., Aug. 30, 1917.

provocative Wassermann test, which will be positive after the administration of salvarsan or neosalvarsan, if the test has been negative after a course of treatment.

The technique which I have employed has been that of a sheep hemolytic system with an antigen which was an alcoholic extract of the human heart reinforced with cholesterine.

The Specificity of the Wassermann Test.—In my experience I have found that only a very few of the known diseases besides syphilis will give a positive reaction—leprosy and malarial fever in the febrile stage and carcinoma of the gastrointestinal tract. I did not find any of these diseases mentioned that would give more than a positive one plus unless there was a positive history of an initial lesion, and I am of the opinion that the Wassermann test, when properly performed and giving more than a positive one plus, is indicative of syphilis.

The Percentage of Positive Reactions in the Various Stages of Syphilis.—An important question is the percentage of positive results that may be expected in the various stages of syphilis. Practically all observers agree as to the percentage of positives in the various stages and I will only give the percentages obtained in my laboratory in a series of 6,000 cases: Primary, 89; secondary, 96.1; tertiary, 87.4; and congenital, 82.2.

How Soon May a Positive Wassermann Reaction Be Expected After the Appearance of the Chancre?—As would be expected, a certain degree of tissue change must occur before syphilis begins to appear in the blood. Even with the best technique there is a limit to the sensitiveness of the Wassermann reaction, so that, while the antibody may be produced at the very onset of an infection, time and further tissue changes are required before sufficient antibodies are produced to yield a positive complement fixation reaction.

A positive reaction may be secured as early as from three to five weeks after infection has occurred. In such cases, however, it is oftentimes probable that the time of infection really antedates the time given by the patient. Craig has reported a positive reaction occurring five days after the appearance of the initial lesion.

It is generally agreed that a diagnosis should be made as early as possible and vigorous treatment instituted. A Wassermann test may be performed and if it shows a positive result, this indicates the presence of syphilis even if the lesion under suspicion is not specific, the reaction being due to a previous infection. A negative reaction, however, does not exclude syphilis, and, if it is at all possible, a microscopic examination, using the dark ground illuminator, should be made for the treponema. In primary syphilis a microscopic examination of the secretions of the lesions by a competent person is usually more valuable than the serum test. As a general rule, both examinations should be made, especially in patients in whom the chancre is almost healed or atypical.

The cerebrospinal fluid of persons in the primary stage of syphilis will always react negatively. The following table of 100 cases gives the blood findings in the primary stage.

Factors Influencing the Result of the Test.—There are several known factors that markedly influence the result of the Wassermann test, the three most important being—(1) the variation in the amount of complement-inhibiting substances in the patient's blood serum; (2) the ingestion of alcohol; (3) and the growth of various bacteria in the blood serum. These factors will be considered separately.

Week of Disease.	No. of Cases.	Positive.	Negative.	Doubtful.
1½	1	1	0	0
3	4	2	1	1
4	10	7	3*	0
5	8	6	0	2
6	6	6	0	6
8	71	67	2†	2
Total number of cases.....	100	89%	6%	5%

*One alcoholic, positive a few days later.
†Two having had treatment.

The Variation in the Amount of Complement-Inhibiting Substance.—Until quite recently it has been considered that the strength of the Wassermann reaction varied but little, in the same serum from day to day, but I have shown that the blood serum of undoubted syphilitics may, in the absence of specific treatment, give a negative reaction during certain intervals, although previous and subsequent tests are positive. Craig's observations regarding the fact were published in 1914 and were stimulated by the fact that in practice he had noted cases in which the blood serum had given contradictory results within a short period of time. Thus he had observed cases in which the reaction varied from a positive one plus to a negative within intervals of a few days, the patients in the meantime having received no treatment. While such observations are not numerous in practice, their undoubted occurrence caused an investigation of the phenomenon, and for this purpose he selected ten prisoners in the United States Prison at Fort Leavenworth, two in the primary stage, four in the secondary stage, and four in the latent stage of the disease. These men were under the strictest discipline, upon routine diet, and the question of the possible influence of alcohol upon the result of the test could be absolutely excluded. The ordinary technique was used in the performance of the test and samples of blood were collected and tested each day from each of the prisoners. The results demonstrated that the titration of daily specimens of blood serum during each stage of the disease showed great variations in the strength of the reactions, and that these variations occurred without reference to treatment. The experiment demonstrated that this normal variation in the strength of the Wassermann reaction must be carefully considered in using the test in the diagnosis or as a control in the treatment of syphilis.

Craig demonstrated that in one case of primary syphilis a doubtful reaction was obtained on three of seven days, the reaction being positive on five days. In one case of secondary syphilis a negative reaction was obtained on one day, a doubtful on four days, and a positive or double-plus reaction on only two days. In another secondary case a doubtful reaction was obtained on two of seven days. In two secondary cases a positive result was obtained upon every day of the week during which the serum was tested. It would seem that this phenomenon

was more likely to be present in the primary stage, due likely to the few syphilitic antibodies which may be developed daily in the early stage.

Influence of the Ingestion of Alcohol.—Nichols and Craig first called attention to the influence of this drug upon the Wassermann test. They found that the ingestion of alcohol in the form of beer or whiskey, as well as alone, and in amounts varying from 180 to 240 c.c. of whiskey, 90 c.c. or 95 per cent. alcohol, and 700 c.c. of Munich beer, was capable of rendering a positive Wassermann reaction negative, and that the reaction remained negative for several hours after the last dose of alcoholic liquors, and in one case as long as three days. In all these cases the Wassermann reaction was double plus before the administration of alcohol and all became negative within a few hours after the administration of this drug. If this drug influences a double plus to this degree, one can readily see that a one plus or doubtful serum would necessarily give a negative and, therefore, make an accurate serum diagnosis impossible. The following is a report of my personal experience of patients who had taken this drug within twenty-four hours from the time the specimen was taken.

Two cases with secondary rash gave positive one plus on entrance, and two days later gave positive three plus.

Two cases with diagnosis of cerebral hemorrhage, both drunk, gave positive one plus, and two days later gave positive two plus and positive three plus.

Gastric crisis one case doubtful, two days later gave a positive two plus.

Corneal ulcer, one doubtful, three days later gave positive one plus.

Psychosis, six cases, ranging from a negative to a one plus, three days later gave a positive in all six cases.

Syphilitic iritis, two cases, one negative, the other positive one plus, after two days in hospital both gave positive two plus.

Arteriosclerosis, two cases, one negative, one positive one plus, after two days both positive two plus.

The Growth of Various Bacteria in the Serum.—This phenomenon was an experiment which I did with a number of negative sera after taking them to the wards and infecting them with stitch abcesses, appendicial drainage, boils, and infections of various types. All gave positive three plus after twelve hours incubation.

If this agent influences the test, we must be aseptic in obtaining the blood. I have been asked by many physicians how to sterilize their syringes for doing venous section and my instruction has been as follows: The syringe should be washed thoroughly with tap water and then with alcohol. This renders it chemically free from antibodies and then it should be boiled to render it bacteriologically clean. If one is to use a syringe soon after boiling, it is good technique to wash it with sterile salt solution or allow it to drain thoroughly. This also applies to tubes in which the blood is to be sent to the serologist. It is also well to keep the blood in a cool place after withdrawal, in order that bacteria, in case any should be present, may not multiply, and thus give a false reaction.

The Provocative Wassermann Test.—This method of applying the Wassermann test is of the utmost value in the diagnosis and control of the treatment of syphilis, and while it has been most intensively used in deciding whether a patient is or is not cured of the disease, it is also a most valuable diagnostic test, and should be applied in every case where the Wassermann test is negative but there is good reason to suspect syphilis is present.

In 1910 Gennerich called attention to the fact that patients previously treated with salvarsan or other drugs and who gave a negative or very weak positive reaction in the blood, became strongly positive after a dose of salvarsan, the blood being tested daily for at least a week after the administration of the drug. His observations were soon confirmed by Milian, and have since been confirmed by every investigator of the provocative Wassermann test, as it is called, and is now the accepted method of diagnosing and controlling the syphilitic infection.

After the administration of a small dose of salvarsan the positive reaction may occur within twenty-four hours or may be delayed for from three to seven days, and even longer, in rare instances. As the positive reaction may occur within twenty-four hours after the administration of the drug, and as it may be evanescent in character, in properly applying this test it is necessary to make a Wassermann test every day for at least a week, as otherwise the positive reaction may be missed. For this reason the test is not always practicable, but its value is without question, both in diagnosis and as an indicator of the efficiency of treatment.

The following statement appears to be authorized by the evidence that has accumulated regarding this test: In patients who have presented a negative Wassermann reaction for a period of over a year, and in whom symptoms have been absent, the provocative Wassermann test sometimes results positively, thus proving that spirochetes are still present and that the disease has not been cured.

Although this test has been but little used in diagnosis, it is true that a small dose of salvarsan or neosalvarsan, administered to individuals suspected of being syphilitic but in whom the ordinary Wassermann test is negative, will often produce a positive result and thus establish the diagnosis. For this reason I would urge the more general employment of the test in diagnosis, firmly believing that if it were used generally in early primary cases the diagnosis could be made within a week of the appearance of the initial lesion, and that our percentages of positive results in tertiary and latent cases would be greatly decreased. Of course if the dark field microscope is at hand the ideal method of diagnosis in the primary stage is the demonstration of the *Spirochæta pallida*, but in many instances this cannot be done and then the provocative test will prove most useful. In applying the test a great advantage is that only a small dose of this drug is necessary, from 0.3 to 0.4 gms. of salvarsan intravenously being sufficient, and we are not only applying a valuable diagnostic test, but a therapeutic agent at the same time. If we have this valuable aid in diagnosis, physicians who neglect the use of the Wassermann test in the diagnosis and control of treatment of syphilis are doing their patients a great injustice. This test has conclu-

sively demonstrated that many of our clinical conceptions of syphilis are erroneous, that the disease may be present for years without producing symptoms sufficient to attract the attention of the individual affected. If this be so, the supposed cure by mercury and other drugs, even including the best of all specifics, salvarsan, is a dangerous fallacy and syphilis must be regarded as one of the most insidious and persistent of all the infections occurring in man.

THE TABLE OF DIFFERENT NATIONALITIES, WITH POSITIVE REACTION IN 1,681 CASES IS AS FOLLOWS:

Nation	No. of Cases.	Positive History, per Cent.	No History Ascertained or Denied, per Cent.	Positive Reaction, per Cent.	Negative Reaction, per Cent.
American	979	10	90	30	70
English and Scotch	131	15	85	27	73
Armenian	4	0	100	0	100
Irish	51	13	87	26	74
Scandinavian	49	24	76	40	60
Mexican	182	15	85	29	71
Russian	45	17	83	29	71
Austrian	11	0	100	18	82
Dutch	4	25	75	25	75
Rumanian	1	0	100	0	100
French	13	7	93	44	56
Japanese	7	14	86	28	72
German	59	20	80	37	63
Bulgarian	1	0	100	10	83
Greek	6	0	100	17	83
Colored	69	10	90	36	64
Swiss	4	25	75	50	50
Italian	31	2	98	28	72
Turks	3	0	100	67	33
Hindu	2	0	100	0	100
Polish	1	0	100	0	100
Syrian	2	100	0	0	100
Spanish	4	0	100	25	75
Chinese	2	0	100	.	.
Hungarian	4	0	100	0	100
Belgian	1	0	100	0	100
Danish	3	0	100	0	100

The above table is incomplete as I have not been able to go over all the records of the 6,000 cases, but felt that this line of investigation might be of interest, as I have been unable to find anything similar to it in the medical literature.

Conclusions.—If the things which I have mentioned affect the Wassermann to this extent the following factors should be taken into account when one wishes to use the serum test for diagnosis and as a check to treatment:

The time of the appearance of the syphilitic antibody in the serum after the infection varying from five days to several weeks, it must be borne in mind that a negative result may mislead the physician as to diagnosis and that a microscopic examination should be made if available.

The second factor which influences the test is the amount of complement-inhibiting substance in the serum and, as I have mentioned above, the lesion may be fairly characteristic and give a negative reaction when it may be of a specific nature, therefore, to give the patient the benefit of this reaction another test should be made in the days following.

If alcohol influences this test as has been demonstrated, the history of having taken alcohol twenty-four hours before the test should be ascertained and if taken within this time advise the patient to return twelve hours later, in order to prevent the influence of this drug upon the reaction.

If the growth of bacteria influences the negative to positive, then it is absolutely essential to have all needles and glassware bacteriologically clean.

Since we have a method in the provocative test for bringing out such latent antibodies as may be present, this therapeutic agent should be used both from a diagnostic and treatment standpoint.

600 MERRITT BUILDING.

STAMMERING.

BY ERNEST TOMPKINS.

PASADENA, CALIF.

THE article on stammering by Dr. Pacini in the MEDICAL RECORD of May 11, 1918, brings up a wonderful opportunity for the United States in win-the-war work. Up to 1914 Germany led us in the investigation of stammering, but we have a clear field to win all the practical benefits from her work and ours because the old mistakes have become cemented in the German schools as State institutions, whereas we are comparatively free to follow the light. If we fail to seize this opportunity to take the laurels from the German we have light regard for American science and American efficiency.

Let us outline the new view of stammering and then test it by supplementing Dr. Pacini's article by means of it. Contrast with the old view will help us to grasp the new one. The old one was that stammering was caused by a lack; the new one is that stammering is caused by an excess, an extra thing—and that is a mistaken, but not illogical, idea of disability. The complete description is as follows:

(1) By an accident or incident, a child is induced to interfere with his normal speech by a conscious effort. (2) The spasm resulting from the interference attracts ridicule. (3) The child makes further interfering efforts to avoid the ridicule, and the failure of these efforts engenders more, and so on until the idea of speech disability is thoroughly confirmed.

The reader may prove this view in five minutes. Let him do anything which the stammerer does—hold his breath, exhaust his breath, press his tongue against his upper teeth or his palate, press his lips together—and try to talk, and he will find that he is impeding his speech, and anyone looking at him would think that he was stammering. Indeed, if he made the test when his speech was newly acquired, he would soon develop into a stammerer.

In order to avoid unscientific procedure, which has been the universal pitfall in the field of stammering, let us consider what scientific procedure is. Haeckel expresses it well in the following language: "The value which every scientific theory possesses is measured by the number and importance of the objects which can be explained by it, as well as by the simplicity and universality of the causes which are employed in it as grounds of explanation. On the one hand the greater the number and the more important the meaning of the phenomena explained in the theory, and the simpler on the other hand, and the more general the causes which the theory assigns as explanations, the greater is its scientific value, the more safely we are guided by it, and the more strongly we are bound to adopt it."

Let us put the speech interference theory to the test, beginning with the etiology of stammering, which is unexplained. The etiology is a temporary

interruption to speech. In voluntary imitation, the interruption is intentional and unquestionable. In association, the imitation may be unintentional, or may be prompted by the desire to avoid the disorder, a case of which is described by Sidis in the *Journal of Abnormal Psychology*, June, 1917. In stuttering, the interruption is the repetition, which, when visited with ridicule, brings out the stammering. In sickness, fright, injury, hysterics, fainting, and so on, the temporary interruption is the broken speech which follows them. It is significant that Freudeanism, dextrosinistrality, and innumerable other alleged causes do not harmonize with the etiology; but as these causes may be shown to be fallacious regardless of the theory, the theory justifies itself by exclusion of them.

The sex ratio of stammering is readily accounted for by well verified facts, namely (1), the divergence of the ratio from unity in infancy to 1:9 in adulthood owing to (2) the "spontaneous recovery" of the girls. The statistics do not go back to infancy, but stop at school age. However, the trend is unmistakable, and we know that conditions prior to school age are much more favorable to recovery than subsequent conditions, for the school treatment confirms stammering. Conradi says, "Gutzmann gives 2:1 for children, but 9:1 for adults, and says with girls it is more apt to disappear than with boys." The ratio in American schools is, girl stammerers to boy stammerers, 1:3, and the adulthood ratio is 1:9; so, for 9 stammering boys there are 3 stammering girls, whereas in adulthood for 9 stammering men there is only 1 stammering woman. Two girls out of three recover between school age and adulthood. In short, recovery of the girls accounts for the sex ratio, and from that we see that there is no sex determinant of stammering.

Whether the stammerer's nervousness is antecedent or resultant is a much discussed phase of the disorder. Temporary nervousness following shock or illness is a great inducing cause, and that has been considered permanent without due warrant. That the extended nervousness is resultant ought to be evident; for the disorder is a constant mental torture and any animal can be made nervous by constant torture.

Heredity seems to be a view which we shall have to abandon. It rested mainly on the idea of a lack, which idea, and consequently its superstructure, is no longer tenable. The observations which seemed to warrant heredity have long been suspected to warrant other conclusions. This common opinion is expressed by a writer in the "Encyclopedia Medica" as follows: "It is said by many writers to be hereditary, and to occur in families with a neuropathic diathesis. Such an explanation does not cover the whole field. . . It is highly probable that cases of so-called heredity are really to be explained by imitation." There are very many reasons why heredity can not be accepted in the case of stammering: no satisfactory evidence of it has ever been presented; some of the alleged proofs of it turn out to be positive disproofs when they are examined; and no theory of the disorder involving heredity has ever been sustained. (See *Scientific American Supplement*, March 23, 1918, p. 186.)

Health and stigmata of maldevelopment may be considered together. Since they come in the "lack" class they are immediately under suspicion, and investigation justifies the suspicion. Let us take a whimsical demonstration. Suppose that these ailments are connected with the stammering. Combine them. Since almost every investigator has given a list of his own—a recent list contains at least nineteen ailments—the total of all the lists would make the subject a corpse; but this is contrary to the hypothesis that he is a stammerer, so the ailments must be rejected. The claim that preference should be given to some ailments cannot stand, for the evidence in support of one is no better than that in support of another. There is another way of deciding the question. Let us bring a stammerer to a doctor who has established a connection between certain stigmata and stammering. If the connection is valid the stammering should be determinable from the stigmata. Say to the doctor, "We will talk for this man and give you any health information desired; tell us from his stigmata whether he is a stammerer." No wise doctor will meet that test, and whoever does meet it is sure to be discredited. It is unquestionable that stammerers have ailments just as other people do; but no connection between those ailments and the stammering has ever been shown. In illuminating distinction to the labored efforts to establish a connection is Fletcher's conclusion, beautiful alike for its truth and its simplicity, "The subjects are not to be distinguished physically from other people; . . ."

Immorality. A child acquires the unfortunate habit (Scripture) of interfering with his speech. His parents are to blame, for he is too young to be blamed. Immediately he is outlawed; for conventions are unwritten laws, and the speech conventions are made for the other 99 people—not for him. Society is against him on every side. His parents make him talk to callers, run errands, answer the doorbell or telephone; his teachers force him to stand up before a class and exhibit his humiliating affliction, so that the other children are infected and he is confirmed in it, and regardless of clear laws which should protect them even if good sense and mercy do not; his employers require him to telephone, dictate, quote prices, do what any other employee does, or "Out you go"; even those who take his money to cure him teach him exercises which inculcate intensified stammering (Liebmann). Then, when he sees his family in want in spite of strenuous efforts to provide for them, when he is sick with loneliness for someone who understands him; when he wishes to die and has to fight off the inclination to gratify the wish—then someone calls him "immoral." If this is not adding insult to injury, what is it?

Transient amnesia. This theory is notable for two things—the elaborateness with which it was advanced and the ease with which it is exploded. Fletcher has already considered it and its first cousin "Visual Center Asthenia" (see *Journal of Abnormal Psychology*, April-May, 1917). But an elaborate consideration is superfluous. Imitation and association account for much of the stammering—Fletcher and some others think for most of it. But Bluemel, the very inventor of the amnesia theory, says, "The two causes of stammering that do not produce aphasia are association and imita-

tion." What good is a theory that is applicable to only half of the field to which it pertains? His attempt to save his theory by an effort to show that there are at least two kinds of stammering does not help his case, for it indicates that the same sort of logic was used in the original demonstration. It is well known that the stammerer is an adept in the substitution of synonyms. But amnesia, as Dr. Pacini says, is "Incapacity to form an antecedent verbal image." How can one substitute a synonym for a word which he does not know? Bluemel endeavors to show that the "color" of the vowel is the only unknown portion, and that confusion of vowels is common to the stammerer; but the first proposition is built up on dogma, and the stammerer's slips of the tongue are no more than anyone would experience who was strenuously dodging difficult words. It is unnecessary to give the many fallacies of this theory. Dr. Makuen, who took it up with great avidity, dropped it with almost as much. He had to drop it; for it makes the stammerer's trouble auditory, and Dr. Makuen was on record to the effect that examination of 1000 cases of stammering revealed no auditory trouble connected with the affection.

Breathing and articulatory exercises. These are intensifiers of the disorder, as Liebmann showed twenty years ago. Why does the medical profession at large suffer the discredit which accrues to it from persistence in mistaken practice by a very small group of specialists? Putting aside ethics and science and coming down to commerce, the physicians as a whole are losing manifold more dollars by it than a few of them are making. An important field of work—medical inspection in the public schools—may not be closed, but it will certainly be hedged, by the forcing of these injurious treatments into the schools.

Treatment. "Re-educate the stammerer in a new mental imagery." Yes. But it cannot be done in the manner proposed. Rather, the manner proposed does not reduce the stammering. The idea of disability which is the continuing cause of stammering was instilled by thousands of speech failures, and the only way to remove it is by thousands of speech successes. The victim must decline to indulge in the convulsive effort, and then what spontaneous speaking he does contributes to his recovery. The more he increases that spontaneous speech the less slowly he recovers; we cannot say the more rapidly, for the recovery of confirmed cases is never rapid. We are talking now of the real recovery and not of the temporary relief which is so readily produced, which is the support of 99 per cent. of the alleged remedies on the market, and which is so generally misrepresented as cure. The spontaneous speech may be stimulated by environment which reduces the embarrassment. Indeed, efficiency in overcoming the difficulty opens a big field for ingenuity; for the stammerer must live during the greater part of his recovery in a world antagonistic to his speech interest. Just to live in that world, let alone making a living in it, without being forced back into the disorder, requires more sagacity and intelligence than one would imagine.

Dr. Pacini should be commended for using English nomenclature. The German invasion of the field of stammering with the word "stutter" to mean stammer has caused much confusion there, and the quicker we throw it out the better. To complicate further a confused field by a confusion of tongues is anything but scientific.

Just a word, in closing, about the speech-interference theory. It gives us the etiology, the common causal factor, the causes of origin by imitation, sex discrepancy, and many other features which are every day pronounced unknown. Indeed, it satisfies every requirement; so, in the words of Haeckel, " . . . we are bound to adopt it," that is, those of us who are scientific.

A NOTE ON THE TRANSFUSION OF BLOOD BY THE CITRATE METHOD.

By ABRAHAM ZINGHER, M.D.

NEW YORK.

ASSISTANT DIRECTOR, RESEARCH LABORATORY, NEW YORK CITY DEPARTMENT OF HEALTH.

The transfusion of blood by the citrate method is probably the simplest way of transferring blood from donor to recipient. It is, therefore, important that all the technical details of this method of transfusion should be as nearly perfect as possible.

The citrate method of transfusion, as recommended by Lewisohn, seems to the writer to have three radical faults:

1. The use of 0.2 per cent. citrate of sodium for preventing coagulation of the blood. With this concentration the blood often clots in the containers or in the needle while it is being injected into the recipient.

2. The collection of blood in one large container, like a graduate, necessitating the stirring with a glass rod to mix the blood with the citrate solution. This stirring has a tendency to defibrinate the blood.

3. The use of a 2 per cent. solution of citrate of sodium for purposes of citration, instead of a more concentrated one, causing an unnecessary dilution of the blood.

The objection features will occasionally cause the failure of a transfusion and could be remedied by using the following procedure, recommended by the writer in a previous communication on the transfusion of young children by the citrate method. (Medical Record, March 15, 1915.)

1. The blood is citrated with 0.3 per cent. instead of 0.2 per cent. citrate of sodium. The additional amount of citrate of soda is not sufficient to make the blood to be injected more toxic and avoids any possibility of troublesome and dangerous clotting.

2. The blood is collected in a series of 100-c.c. bottles, 60 c.c. being drawn into each bottle. A number of small grape juice bottles will serve the purpose very well. To each of these bottles the necessary amount of citrate of sodium solution is previously added.

3. The use of a 10 per cent. solution of citrate of sodium instead of a 2 per cent. solution to avoid any unnecessary dilution of the blood; 2 c.c. of this citrate solution are added to each of the bottles.

The bottles should be prepared by sterilization,

each bottle being stoppered with a gauze plug. For collecting and injecting the blood a salvarsan cannula or an ordinary needle, gage 15, will be found convenient.

While the blood is flowing in the bottle it is gently stirred from time to time and also after the entire quantity is obtained, so as to insure a thorough incorporation of the citrate with the blood. After all the bottles are filled the blood is passed through a few layers of gauze, moistened with a 0.3 per cent. solution of citrate of sodium, into a single container and is injected by means of a salvarsan apparatus. In an emergency the barrel of a large syringe and a piece of rubber tubing with a suitable needle or cannula will serve the purpose very well.

DEATH FROM VOLVULUS CAUSED BY ROUND WORMS.

By VICTOR G. HEISER, M.D.,

NEW YORK.

Dr. John F. Kendrick reports the following case from the Seychelles Islands:

A child four years of age was given six minims of oil of chenopodium. Two days after the administration of the chenopodium the child was reported very ill. There was marked distention of the abdomen, with severe pains, frequent vomiting, and the bowels had not moved since the day treatment was given. On post mortem a mass of round worms the size of a man's fist was found blocking the bowel; the intestines below the mass were so twisted as to cause complete obstruction; there was local peritonitis in the vicinity of the obstruction, and more than 300 round worms were found in the intestinal canal.

Medicolegal Notes.

Malpractice—Insufficient Evidence of Negligence.—In an action for damages alleged to have been sustained because of the unskillful and negligent manner in which the defendant, a practising physician, reduced and treated a fracture of the radius of the plaintiff's left arm, the allegations of negligence were: First, that the defendant was negligent in not reducing the fracture properly; second, that the defendant was negligent in using only pasteboard splints at first, and afterwards inadequate and improper splints, and in not applying proper bandages and appliances to keep the broken bone in alignment or proper apposition. There was no direct evidence showing that the fracture was not properly reduced. There was no direct evidence that the broken parts were not put in proper apposition. There was no direct evidence that the splints and bandages used were not the appliances ordinarily used by physicians and surgeons in the treatment of such fractures.

A physician is held to the exercise of the skill and learning of the profession generally in the community in which he practises. The case was purely a fact case, with the burden resting on the plaintiff. At the conclusion of the testimony, the court directed a verdict for the defendant. The plaintiff appealed. The Iowa Supreme Court reviewed the evidence in detail and summed up as follows: "There are authorities saying that where the condition found upon an examination is of such a character, so out of harmony with conditions that ought to exist under proper treatment that a physician, seeing the result, may as an expert testify that the proper treatment was not administered or such a result would not be found. Now, it is true, as a general proposition, that the result furnishes no evidence of negligent treatment, but some cases may arise where evidence of the poor result alone might convince an expert that the treatment must have been improper. An opinion based upon such a showing would be competent evidence to establish the ultimate fact charged in the complaint.

"But such a case is not before us here. The only expert called by the plaintiff who is shown to have been in a position to know just what the condition of the bone was after it had healed and the manner in which the fracture was reduced is Dr. Crenin, and he tells us that he found the bone in proper apposition and properly healed; that the alignment was as good as you could expect under the conditions which he found there. The only condition which he found that required treatment was the callus which nature throws out and over which the attending physician has no control. It seems that an excessive amount of callus had been thrown out around the wounded part. The excessive callus, as this record shows, may be due to many causes, none of which are under the control of the attending physician, and a careful examination of the x-ray pictures shows that the deformity appearing in the pictures is caused by the excessive callus and which, when removed, left the arm with all its functional properties normal. It is apparent that the plaintiff relies upon negligence—negligence of the attending physician in the treatment of the arm. It rests on the plaintiff, therefore, to show affirmatively that the condition of which he complains was due, at least in some measure, to the negligence of the physician in respect to the matters relied on as constituting negligence. A verdict to the effect that the doctor was negligent in reducing the fracture or negligent in the treatment of the fracture after it was reduced would rest necessarily upon mere speculation. The evidence pointed to no act of negligence on the part of the defendant. Every doctor who testifies or assumes to say that the result was not perfect tells us in this record that, even with the best treatment, with the fracture perfectly reduced and proper bandages and appliances to keep it in position used, the condition here found might fairly be expected." Judgment for the defendant was affirmed.—O'Grady vs. Cadwallader, Iowa Supreme Court, 166 N. W. 755.

Hypothetical Questions.—Objections to a hypothetical question put to a physician concerning the plaintiff's injuries that such question did not embrace all the facts shown by the evidence, but which failed to point out what facts were omitted, were held unavailing. In a street car passenger's action for injuries, testimony had been admitted but later stricken that she suffered three fractured ribs. It was held that a hypothetical question put to her physician whether the accident alleged could have produced the conditions visible when he examined her was not erroneous as permitting an answer based upon the rib fracture; such not being visible.—Shafer vs. Kansas City Rys. Co., (Mo.), 201 S.W. 611.

Corporations for Pecuniary Benefit.—The Illinois Supreme Court holds that a medical association organized for the advancement of medical science and to improve methods for the treatment and prevention of disease is not a corporation for pecuniary benefit under sections 1-28 of the Illinois Corporation Act, and may elect its trustees through delegates without the limits of the state, in view of section 32 and the by-laws of the association.—People v. Grant, (Ill.) 119 N.E. 344.

Certificates of Qualification.—The Alabama Court of Appeals holds that requiring a certificate of qualification from persons proposing to engage in the practice of treating diseases as a profession and for a livelihood is a police regulation designed to protect the public from the ignorant and incompetent, and the Legislature may prescribe a test to determine qualification, and confer authority on a designated board, to conduct the proper examination through which the test may be applied, as is done by the Alabama statute denying the privilege to such persons without a certificate from the "state board of medical examiners," and a chiropractor not being excluded or discriminated against, and having equal right to apply for a certificate, is not exempt from the operation of the regulation.—Williamson v. State, (Ala.) 78 So. 308.

Military Medicine.

SYMPOSIUM ON MILITARY SURGERY.

THE meeting of the Section on Surgery of the Medical Society of the State of New York, held on Thursday, May 23, was devoted to papers and discussions on Military Surgery. Dr. Thomas F. Laurie of Syracuse was in the chair.

Treatment of Gunshot Wounds of the Humerus.—Captain G. E. WILSON of Toronto, Ont., presented this subject (by invitation). He showed a wire splint devised for fractures of the humerus. This was supported by a plaster bandage around the chest and by a shoulder strap. If the plaster slipped the shoulder strap could be adjusted. This gave absolute fixation, movement being limited to that of the subcutaneous tissues on the deep fascia of the ribs. One point that always seemed to help the wounded soldier was to let him have a cigarette while the plaster was being applied. No matter how wornout he was, this would generally help him to smile. When the splint was adjusted, the patient could be treated as a walking patient and be transported in a lorry. This was an economic saving. The splint would carry the weight of the arm, by support from the chest, and thus relax the shoulder girdle muscles. As there was no traction upon the axilla, the splint was applicable to compound fractures. With pressure on the axilla, there was not good extension. With a large wound posteriorly, the flannel supports across the splint were arranged so that the wound could be dressed. If the *x*-ray showed imperfect alignment, the arrangement of the armpiece on the chestpiece could be altered. A test as to the proper arrangement of the splint was, that if in proper position, one could shake the patient and the movement would cause no pain. To prevent slipping, the shoulder straps were embedded in the plaster.

Treatment of War Wounds.—Major C. L. GIBSON, M. R. C., made this presentation. He said that the surgery of civil life did not apply at all to the conditions of modern warfare. The deep trench fighting made of the soldier a filthy and contaminated person and the elements to be dealt with in treating the wounded had no counterpart in civil life. Fear, lack of food, shock, multiplicity of wounds, the tedious and dangerous journey from the trenches, all tended to complicate the patient's condition. Three elements had to be combatted—shock, hemorrhage and sepsis. Sepsis was an active element in one hundred per cent. of cases. In order to overcome this, early treatment was of the first importance. Wounds had to be freely laid open and all foreign bodies removed. Surgeons were seeing the necessity of moving the line of relief nearer to the battlefront and good surgery could now be done near the line. The removal of foreign bodies and of damaged and necrotic tissue was effected as soon as possible. Until this was done the use of the Carrel Dakin method was of little avail. Combined with free excision it gave good results. Good surgery, at an early stage, was the *sine qua non*. The special technique necessary for the Carrel Dakin method made it unavailable for a large number of wounded. The methods carried out at present were simple and avoided complications. A radical excision of all bruised tissue and foreign bodies was made at the clearing station, 10 miles back of the line, where a 200-bed hospital was established. The wounded were first brought to dug-outs for first aid, then taken to a dressing station 3 miles behind the line. They were kept warm and comfortable in the waiting room and any treatment that could be done under local anesthesia or nitrous oxide was undertaken. A resuscitation ward had special resources for caring for the wounded. Plenty of fluid was usually given on account of the dehydration of the patient. The more serious cases were given surgical attention first. Badly shocked patients were taken care of at once. Surgical teams, accustomed to work in cooperation for many months, handled the operating, often several teams in one large theater. In the so-called "peace" times, *x*-ray studies were made. The French excelled in their fluoroscopic apparatus. They were accustomed to swab out wounds with some antiseptic, the most popular being ether. The British used 1 per cent. iodoform. The head wounds and abdominal cases were always treated first. They were kept in the hospital one week and then moved back to the base hospital. The results of this procedure were generally good. Primary suture of wounds was now usually practised, after thorough surgery. If the cultures showed streptococci or the Welch bacillus the wounds were left wide open. The French had their base hospitals nearer to the front than the British. The further one got away from the battle line, the more conditions resembled those in civil life.

Development of a Military Roentgenological Service in New York City.—Dr. L. T. LE WALD of New York presented this report. He said that the profession in America had the advantage of the experience of French and British medical men. A roentgenological service had been organized for the army, just as had been done with other branches—orthopedic, neurological, or pathological. Different forms of apparatus had been devised to meet the situation. An electric vibrator had been devised to supplement radiographic diagnosis, by the oscillations of which the presence of a foreign body could be detected. Another of these accessory methods was the telephonic localizer which would show by a clicking the neighborhood of a metallic foreign body. When working with the fluoroscope the surgeon wore an adjustable hood through which he could make the fluoroscopic examination, and which he could turn back over the head and continue the operation. The Sutton method was by a sort of fish-hook, which caught in the tissues and came in contact with the foreign body. Alfred Taylor had devised the use of a stiff wire, instead of using a cannula. The Hertz compass was also in use. This pointed to the projectile. A peculiar type of angular forceps was used, when removing the foreign body, under the fluoroscope. These did not interfere with the direction of the ray. A portable Coolidge tube was also in use, and a portable *x*-ray apparatus for bedside work. Major Paul had invented a stereofluoroscope, in which two tubes worked exactly alike and by means of which the surgeon and the roentgenologist could both work together in locating foreign bodies. At Cornell Medical College, at the present time, Dr. Le Wald said he had just completed the training of 500 roentgenologists to supply the government demand for that equipment, to go with a force of 1,000,000 men. This staff was now ready for work. He would like to know if Captain Wilson's splint could be made in aluminum.

Dr. R. H. SAYRE of New York said that in examining Captain Wilson's splint, he thought that the patient might buckle with the weight of the arm. Would not the support be increased by running it down so as to gain the support of the pelvis. It seemed as if that might get better traction against the entire chest wall.

Dr. G. D. STEWART said he thought most people had an idea that army surgery was a rough and ready business. The army, however, had the largest and best equipped surgical laboratory in the world. It was interesting to note that in the treatment of fractures 400 years ago Ambrose Paré poured boiling oil into wounds caused by gun shots. John de Vigo at the siege of Milan wished to follow this treatment. The supply of oil running out, he poured in white of egg and turpentine instead, and, his conscience troubling him in the night (like many of his successors), he got up to see how the men were doing without the oil. To his surprise he found that they were doing much better than they did with it. This early treatment was along the line of antisepsis. They should feel indebted to Dr. Martin for grouping the treatments. First, use of sera, which had not gone very far; second, the use of antisepsis, which was about equivalent to Lister's work; third, use of free excision, which was a distinct advance. Most of the profession had come to that conclusion.

Dr. WALTON MARTIN of New York said that the value of the *x*-ray examination in modern surgery in regard to excision of the wound tract was to be emphasized. Men were injured in every possible position and it was difficult to see the direction in which the bullet traveled. A man might be hit in a crouching position and the bullet would take a curious route. In regard to the historical points, a history written in the second century

dealt with injuries by bullets of lead from a sling. A chapter mentioned the disadvantages of leaving them in the tissues.

Capt. G. E. Wilson said that aluminum would not be strong enough for the arm splint unless a considerable bulk were attained. This would not be as easy to handle. The stereoscope could be used for getting good position of the fragments. Dr. Sayre suggester strapping the support lower down on the pelvis. The plaster was put on to stop the movement of the dorsolumbar vertebræ. It was necessary to put the plaster on with the spine in correct position, and if this was done the patient did not buckle.

The Medical Section of the Council on National Defense.—Dr. George David Stewart of New York presented this address. The Council of Defense for New York State, he said, had instructions to add to its membership, the only limit being unwieldiness. Each member had to be recommended by a sufficient number of good men, but not so many as were necessary to save Sodom. It was as important to get good men as it was to prevent undesirable men from getting in, and this side had also received attention. Women members were now to be added to the council. The Council of Defense was merely missionary in character and extraconstitutional in action. It controlled by *impression*. Its function was to present to the doctor the medical necessities of the Government and to present to the Government the medical help that it needed. The first effect that was produced was by starting men to *think*. In New York State a medical census was taken and an idea obtained of, for instance, how many one-legged, blue-eyed orthopedists could be commandeered in the Empire State. The personal touch was heeded in these inquiries. How much trouble a man had with his mother-in-law was taken into consideration. County committees were formed and now every county had two or three representatives who were part of the auxiliary Council on National Defense. Confidential information was furnished and spread of propaganda undertaken. The potential effect of a selective draft was considered and measures taken to preserve teachers, health officers, and men necessary to the community for work at home. The idea of conscription, allowed at one time to fall into innocuous desuetude, had lately again been discussed. It was considered likely, however, that the volunteer Medical Service Corps would be sufficient. New York State had given more than its quota of men to the Medical Reserve Corps, but still it had not the top place. When the war broke out there were 435 men in the medical service of the army. Now there were 22,000 doctors in the service, and that without conscription. The Government needed 7,000 more by the first of July and of these New York State had to contribute one-tenth. With such a leap of numbers, from 435 to 22,000, it was only human that there should be some mistakes, some clogging of the machinery. Still, the profession had to face the problems of the future. Most of them were apt to look upon America as the land of promise, the land where one who was willing to work would achieve success. The Atlantic Ocean had made this possible, had made the Monroe Doctrine possible—in fact, the Atlantic Ocean *was* the Monroe Doctrine. This feeling was in the blood of every American. It was a good country to live in, but it was going to be better. If this was to be true, every American had got to take thought how it was to be brought about. The tendency of all nations was to rise with strife, but to relax with comfort. Spring was the time of effort, but after the fullness of summer followed the winter and death. This was the inevitable law. None of them wanted the spring of this country's life to be too short. The lessons of patriotism, taught by an enforced military training, were tending to make America more of a nation. The war was giving a new bill of health to ten million Americans. Those fit for class two would be trained and made fit for class one. This war was forming a new post-graduate class for most of the medical profession in America. America had been spoken of as the "melting pot"; the war was starting new fires under the melting pot and it was bubbling up to a new nationalism. It had been a great country, it would now be a great nation. Those to go to the war should be the young men of good training and good health. The old should do the work at home. The young man with moderate practice did not make such a great sacrifice of his professional prospects; indeed, he often improved his standing. The question of love of wife and children had to be balanced with love of country. The American had to ask himself, "Do I care to live if my country is in bondage?" If he did care to do so, he was not an American. In every mind there was a willingness to follow an ideal. This it was which distinguished man from the animals. It was a Canadian doctor, who had died in the early days of the war, who wrote:

"Take up the torch and bear it high.
If ye break faith with us who die
We shall not sleep, though poppies grow
In Flanders fields."

They who had lived in the Land of Freedom could feel the truth of Kipling's message:

"There's but one task for all;
There's but one life to give."

Now, as before, they would answer the battle cry of freedom and answer to Uncle Sam, "We are coming, fifty thousand strong."

Needs of the Medical Reserve Corps.—Major S. S. Simpson, M.R.C., presented this address by invitation. The problem of the medical needs of the army was a very large one. There were four basic factors to be considered: (1) The impossibility of considering any victory except upon the basis of enduring peace; (2) the need for equipment of a large army, such as was asked for by the President; (3) the medical corps of the army should be composed of volunteers and the task of providing officers fell upon the medical profession; (4) the fact that the enemy was trying to undermine the confidence of this nation as had been done in Italy and Russia. Prussian autocracy, by repetition of words and phrases, was trying the same trick in America. This attempt to retard preparations here, by making believe that Germany was weak and ready for peace, should deceive no one. The President did not believe this and now, if any, was the time to strike. An army without limit was requested and needed. It now fell upon the medical profession to furnish advisors for the army force. The integrity of the nation was seriously threatened and all resources should be commandeered. If volunteers failed, the nation would have to resort to conscription. This probably would not be necessary as the profession were met to consider what measures could be taken to meet the needs of the Government. Splendid work had been done in New York State, but many other States were doing as well. The surgeon-general had issued a call for 8,000 medical officers. This did not mean in the future, it meant *now*. The Navy needed 1,000 medical men at once. A knowledge of the nation's resources and a wise use of them was therefore essential. A comprehensive classification had been compiled one year ago, and was revised from time to time, dealing with material needs as well as with personal. As new troops were called, new medical officers were wanted. An assurance was needed, and was given, that positions should be undisturbed during the war and that men should return to them again. Individuals would do well to put their affairs in order so that when called they would be able to respond. The peace needs of the army were for 7,000 doctors to 1,000,000 men and the war needs of the army were 10,000 doctors to 1,000,000 men. Twenty thousand medical men had been recommended for the Medical Reserve Corps, but of these many were not available for service, some being with the Allies, some not being physically fitted for service. It was as necessary for the Surgeon-General to have a surplus of doctors as for a bank to have a surplus of funds. The appeal was made to each man to take this matter as one of direct personal moment to himself. Some could not go, but they could see that other men were sent. No man was absolved from duty to the nation. All must do their share to win, and have confidence in winning. He could not quite agree with Dr. Stewart that the Committee on National Defense was unofficial. It was authorized by the President, and each State and county committee constituted part of the Federal Government. It was not necessary, however, to have this made a federal thing. The medical profession was doing it, and would continue to do the work successfully to the conclusion of the war.

Meningitis at Camp Greene. — Cerebrospinal meningitis has been unduly prevalent in many of the training camps of this country during the past winter, and therefore any data concerning the diseases which appear likely to elucidate its obscure and moot features, thereby rendering its control more easy, should be carefully collected and earnestly studied. Capt. Paul G. Wooley, M.R.C., writes in the *Journal of Laboratory and Clinical Medicine* regarding conditions at Camp Greene. He says that cerebrospinal meningitis was at no time truly epidemic in that camp, for during a period of something over two months only thirty cases occurred in a camp population varying between 30,000 and 40,000. Under the conditions of camp life such as prevailed during the past winter, with exceedingly cold weather, with sleet and rain alternating, with the men practically living in the mud, wet from one day's end to another, huddling together for warmth, in other words with all the most favorable conditions for the transmission of infection, such an incidence cannot be called epidemic. As a matter of fact, it was surprising that the sick rate was as low as it was, and the comparatively slight amount of disease that occurred from all causes spoke well for the care exercised over the men. Cases of meningitis began to appear in December, 1917, and after the appearance of the first case continued to come sporadically during January and February, 1918.

The only available statistics at hand indicate that there were between 5 and 7 per cent of carriers at Camp Greene. These figures came from the detention camp and are therefore too high, in all probability, for in this camp all meningitis carriers were isolated pending bacteriological examination. It would appear, therefore, that the percentage of carriers was smaller than in other camps. However that may be, it represents after all merely a guess, because the only organizations which were cultured were those in which meningitis appeared and probably represented not more than half the personnel of the whole camp.

More interesting is the fact that in the only organization which made use of systematic nasal sprays from the first of the year not a single case developed, and also that in those organizations in which the use of sprays were resorted to after the appearance of the disease no other cases appeared. This might be merely a coincidence, but when one discovered that also following the adoption of sprays the total sick rate fell, especially that due to respiratory diseases, and bore in mind the current conception that the menigococci inhabited the nasal passages, one came to have a very healthy respect for dichloramine-T as an agent for the prevention of diseases originating from the upper respiratory tract. From his experience in Camp Greene, Wooley recommends the routine use of dichloramine-T nasal spraying as a prophylactic measure for respiratory diseases, especially in military camps.

Hospital Ship Torpedoed Without Warning.— The Canadian hospital ship, *Llandovery Castle*, was sunk without warning by a German submarine off the southern coast of Ireland on June 27. Of 250 persons who sailed on the vessel only 24 are alive. This latest crime of the German submarine was even more wanton than those that have preceded it, for after sinking the ship the enemy fired on life boats filled with survivors and even pushed off the victims of their inhumanity from the wreckage to which they were clinging. Most of those aboard the vessel were Canadian Red Cross men and women. The attack on the survivors was evidently made with the object of wiping out all trace of the crime.

Widening the Activities of the U. S. Public Health Service.—President Wilson has placed all sanitary and public health activities carried out as war measures under the Public Health Service.

Veterinary Force Sufficient to Meet the Needs of the Army.—There is available a force of veterinarians sufficient to meet the needs of the army for some time to come. Examinations for commissions have been closed. In addition to the 1,700 officers and 10,000 enlisted men on active duty there is a waiting list of men who have passed the examinations and who will receive commissions when vacancies occur. A training school for commissioned veterinary officers on active duty has been established at Camp Greenleaf, Chickamauga Park, Ga., from which one hundred men are graduated every month, after having received a two months' special course.

Lutherans Offer New Hospital for Soldiers.— A resolution was passed by the Board of Directors of the Lutheran Hospital of Manhattan, on July 2, offering their hospital building at Convent Avenue and 144th Street, as well as their nurses' home nearby, to the Government as a hospital for wounded soldiers returning from abroad. The building has accommodations for one hundred patients.

Captain E. J. Presper of the Medical Reserve Corps, attached to the British Expeditionary Forces, is reported by the Adjutant General's office to be a prisoner in Germany.

W. M. Wood Gives Convalescent Hospital.—A large Red Cross convalescent hospital has been established by William M. Wood on his estate at Cuttyhunk, near the mouth of Buzzards Bay. The hospital will accept as patients officers from all branches of the service, both of the United States and her Allies, who need rest to put them in shape for further service. Dr. Norman E. Ditman is medical director of the hospital.

Women Workers to Treat Gas Cases.—The Women's Overseas Hospital, which has now some thirty women physicians, nurses, and aids in France, has been asked by the French Government to send immediately fifty women to run a hospital of 300 beds about to be established for the treatment of gas cases. Dr. Alice Gregory who headed the civilian unit of the Overseas Hospital, has gone to establish a hospital at the front and will be succeeded by Dr. Marie Formad of Philadelphia. Mrs. Raymond Brown, who has just returned from France to recruit the unit, states that there is a great field for women dentists among the civil population of France.

Hospitals for Americans in London.—The British Army Council announces that the Red Cross will take over two London hospitals for the exclusive use of American wounded.

MEDICAL RECORD.

ECONOMY IN MEDICAL MATERIAL.

THE time is surely coming, if the war continues as long as it now promises, when the shortage in army medical officers will become acute, unless steps are taken in time to prevent it. We sometimes think we have done pretty well in furnishing the present army of two million men with the necessary doctors, but that is only two-fifths of the army that it is estimated we shall need in order to put an end to the crimes of Germany. That means that nearly thirty thousand more physicians must volunteer, and this without counting those needed for the constantly growing navy. Where are these men to come from? There are, roughly, about 140,000 physicians in the United States, over 20,000 of whom are already in the services, leaving less than 120,000 to be drawn from; therefore at least 25 per cent. of the medical men now in civil practice must enter the army or navy.

This will mean inconvenience and hardship for many, but it must be, and the only problem is to effect the necessary readjustment with as little disturbance as possible. That calls primarily for the greatest possible economy in medical material. There is a large number of physicians in the country who are anxious to do their part but whose offers of military service are rejected because they are over 55 years old; yet hundreds if not thousands of these "superannuated" physicians have the physique and possess medical skill amply fitting them for service in base hospitals in this country, while others could do much of the clerical work which now keeps many younger men of superior attainments from doing that for which they have been specially trained. Other over-age men who are not fit for such work or who could not for one valid reason or another undertake it, are perfectly capable of discharging the duties of attending physicians and surgeons in the civil hospitals of the country, thereby freeing a host of younger men constituting capital material for army or navy service. Then there are 5,000 women physicians in the country, many of whom could fill responsible positions in base hospitals here and abroad and on the staffs of civil hospitals.

A plan of economy in hospital service has been suggested by Dr. S. S. Goldwater, chairman of the war service committee of the American Hospital Association. In an appeal recently made to the hospitals of the country, he has urged that they put themselves on a war footing by abolishing the rotating service, substituting therefor a plan of continuous service, thus releasing a large number of competent men for the country's need. The rotating service is one which is filled by a certain number of men each serving a certain number of months only in each year, and this plan Dr. Goldwater would do away with for the period of the war. "In this crisis," he writes, "no plan of organization is admissible which does not release every competent physician who can be spared for military duty," and his slogan is, "One job, one man!" This would doubtless release a number of men of army age, but there are objections to it. In the first place a large and active hospital service is too much for one man to care for twelve months in the year. The sole attending physician or surgeon would have to be a young and physically strong man, just the kind of man the army needs. Then, again, should he die or be suddenly incapacitated, the hopsital would suffer until a capable successor or substitute could be obtained. Of course, he would have to have an assistant or understudy who could act in such an emergency, but there again would be a good man kept out of the army. A better plan, we venture to think, is the one above suggested, of raising the lower age limit of the attending staff, keeping the rotating service as it is, but calling to it only men over the army age. Many such are even now in hospital service, and the places of the younger members of the staff could readily be filled temporarily by older men, many of whom have had a long hospital experience and who had retired only to give the younger men a chance. Some men who have retired may not relish being drafted for service again, but every man must do his part in winning the war and that will be theirs.

THE PSYCHIC DISTURBANCES OF LOCOMOTOR ATAXIA.

IT is quite essential to make distinctions among the psychic disturbances which may be met with in cases of locomotor ataxia, not merely as to their nature and the place they may occupy in mental syndromes, but also and above all on account of the relation of causality uniting them to tabes. In the first category should figure those cases of mediocre interest in which psychosis of some type, present before or after the development of the tabes, is related to the latter process by no etiological circumstance whatsoever. In these cases of simple coincidence, the sensitivo-sensorial or motor disturbances of locomotor ataxia may, nevertheless, exercise an accessory or secondary influence on the delirium, either by imparting to it a particular shade or by being the starting point of an erroneous diagnosis.

Locomotor ataxia may be an occasional factor in the awakening or manifestation of psychoneuropathic manifestations, such as neuresthenia or psychasthenia, particularly a phobia of the equilibrium or the gait. But these instances being eliminated, it is at present a universally established fact that the vast majority of psychic disturbances encountered in tabes belong to an associated general paralysis, anterior or contemporaneous with, but usually following upon the meningo-radiculo-medullary process. Amaurotic locomotor ataxia, in which mental disturbances are particularly common, would appear to confirm this opinion.

In addition to the foregoing, however, many other psychopathic manifestations should be looked upon as having a direct etiological relation with locomotor ataxia. Such are changes in character or moral disturbances, psychoses of the depressive type with psychosensorial disturbances, paroxysms of excitation with a delirium of megalomania, and deficient states, commonly called tabetic dementia. It would appear that the first three of the above-mentioned disturbances have when first observed, or soon afterward assume, the characters of psychopathic states developing on a more or less distinct basis of intellectual weakening, so that they finally enter the fourth category, namely, tabetic dementia. Thus, if associated general paralysis be eliminated, the entire question of the existence of the mental disturbances of locomotor ataxia is reduced to existence of a tabetic dementia quite distinct from general paralysis. According to a number of writers tabetic dementia is differentiated from paralytic dementia by a number of physical and psychic signs. There is no disturbance of speech, or if it does exist, it is very slight. The dementia is less profound and not so rapidly progressive, and often undergoes quite long remissions. But these clinical characters are encountered in certain instances of general paralysis, so that they do not offer a sufficient ground for differentiating with certainty between tabetic and paralytic dementia.

Pathological anatomy and histology are unable as yet to serve as a criterion for diagnostic differentiation. In certain cases of tabetic dementia clinically characterized lesions of chronic diffuse meningoencephalitis, identical with those of general paralysis, will be found at necropsy. In still other cases the lesions, although retaining the same type, are less diffuse and recall those found in certain cases of luetic meningoencephalitis, intermediary between cerebral syphilis properly speaking and the diffuse meningoencephalitis of general paralysis. Finally, the common lesions of arterial atheroma, softening and senile degeneration are present.

It would, therefore, seem logical to conclude that in the vast majority of cases the demential psychoses of tabetics are chargeable to general paralysis. Sometimes the condition is one of syphilitic meningoencephalitis, which is as yet ill-defined from the viewpoint of clinical symptomatology and to a certain extent realizes the Guillain-Thoan syndrome, which is met with in conditions other than tabes. Finally, it may be an ordinary dementia resulting from arterial or senile lesions.

FIBROID INDURATION OF THE CORPORA CAVERNOSA.

Sclerosis of the corpora cavernosa affects various forms but it is usually found as small hard nodes, generally sunk in the midst of the erectile tissue, which are found only upon examination. These nodes may vary in size from a cherry-stone to an olive, but usually they are much smaller. They may occupy one or both corpora. When the penis is flaccid they are invisible but are readily palpated. In most cases they are separated from each other by apparently healthy tissue, but they may be united by fibrous bands, giving a hard, sclerous feel to the entire corpus cavernosum. These sclerous formations are embedded in the midst of the erectile tissue like a foreign body and have no connection with the urethra, glans, nor albuginea of the corpus cavernosum. The process preferably occurs in the superficial portion of the erectile tissue but does not become adherent to the enveloping membrane in most cases. The nodules are absolutely indolent and never give rise to inflammatory reaction.

The development of the sclerosis is insidious and it is only after a time that it is noticed by the patient during erection, because the penis becomes laterally curved, a condition that the immortal Ricord was pleased to call strabismus of the penis. Occasionally the normal curve of the member is accentuated but the lateral deviation is by far the most frequent. The deformity is all the more pronounced the nearer the sclerosis masses are to the base of the corpora cavernosa, and besides the deformity occurring during turgescence of the penis there are also a decrease in the caliber of the organ at certain points, a weakening of the erectile rigidity, and a collapsus of the genesic sense. From all this, more or less serious disturbances accrue which hinder or prevent coitus from taking place and at the same time exercise an unfortunate reflex psychic action on the morale of the patient.

The causes of this interesting process are still obscure. According to some writers the morbid production is due to gonorrhea, traumata, senility, or certain diatheses, such as gout, arthritism, or diabetes, but it is also an unquestionable fact that sclerosis of the corpora cavernosa may be purely and simply a tertiary syphilitic process, as shown by the cases reported by Arion in his recent thesis (Paris, 1916). Besides the ulcerating tertiary syphiloma or gumma syphilis produces other essentially sclerous lesions which are all the more prone to follow this evolution, the greater the vascular supply to the structures involved. The erectile tissue of the corpora cavernosa fulfills these conditions to a nicety, therefore it is only natural that the luetic virus should set up the usual sclerotic process

in it by vascular irritation. As a matter of fact, ulcerating gummata are never met with in the erectile tissue.

The evolution of cavernous sclerosis is exceedingly slow, but its progress is influenced by antisyphilitic treatment, and although a complete and permanent cure of the process cannot be obtained, at least a marked improvement in the condition may be effected if the treatment is begun before the sclerotic process has gotten well under way. If the etiology of the sclerosis is uncertain it is well to make a Wassermann test and if even then the result is doubtful a test treatment should be essayed, which although it may not result in anything tangible will at least have a happy effect on the neuropathic state of the patient.

THE VAGINAL DOUCHE.

THE antiseptic vaginal douche has become such a common and popular method of treating all pelvic ills of the female, especially by the laity, that the indications and the dangers from its use have been quite overlooked. The indiscriminate use of the vaginal douche for general cleansing purposes regardless of the presence of pathological conditions, this being often advised much in the same way as the bath, is, unlike the latter, an uncalled-for interference with natural conditions. The vaginal secretions and the flora are protective rather than harmful. The saprophytic organisms contained therein are inimical to the development of pathogenic organisms, and the removal of these secretions by the douche leaves the vaginal mucosa unprotected and more easily subjected to trauma and infection. The chronic douching habit has probably as much to do with cases of idiopathic sterility as any other conditions. It is a fallacy to believe that the vaginal mucosa has little absorptive power, and that any antiseptic solution short of a caustic can be used with impunity. In the first place, any antiseptic that is physically destructive to the organisms contained therein is also physically destructive to the tissues. In the second place, disease is more likely to occur from introduced infection not successfully removed by the douche than if under the same circumstances no douche had been employed. But even if all infection is removed by the douche, the injury of the mucous membrane and the removal of the protective secretion make infection from outside sources very likely. The use of strong antiseptic solutions of bichloride, carbolic acid, etc., may harm the organism through absorption. Frank cases of poisoning are frequently reported.

When the object is to destroy pathogenic infections occurring in the genital tract, the methods of dry cleaning are far more effective and without the objections to the vaginal douche. Dry cleaning cannot so easily speed the infection to other parts of the tract as it must be obvious the douche so often does. Nevertheless, the hot vaginal douche has a use in pelvic inflammations through the production of pelvic hyperemia. But as a matter of fact, whenever the hot vaginal douche is advised only a warm douche is given. The warm douche tends to encourage congestion, the very thing to be avoided. On the other hand, even the warm douche has its place. It can act as a poultice or fomentation in cases of pelvic disease when the hyperemia produced aids in the absorption of the pelvic exudates. But both the warm and the hot douche must have a clear therapeutic indication if their use is to be productive of good.

COLORED HEARING.

THIS most common of the synesthesias now has a large literature, but few truths can be uttered in respect to it, on account of its individual and impressionistic character. In the issue of the *Journal de Médecine et de Chirurgie Pratiques* for May 10 is a brief account by Professor Blanchard of some old episodes of this character. About a dozen years ago he assisted at a concert at Egyptian Hall, London, in which while a piano was played in the dark each note was represented by flashing an incandescent light in a specially colored bulb. The same note was always indicated by the same color. The experience was a novel one, and many of the audience-spectators professed to be able to experience the same pleasure from the harmony of the colors that others feel from the harmony of sounds. The author does not know whether the "chromatic" scale of the lamps was arbitrarily chosen, or based on a quasi-musical notation. More recently (1913) a similar concert was held, also in London, which the author knows of only from the press. In this case there was a demonstration of an organ in which pressure on the keys caused colored lights to flash on a screen. The organist executed color symphonies which gave to some of the spectators pleasure analogous to that of musical symphonies.

News of the Week.

Disease in Germany.—A recent message from Berlin states that there are approximately 100,000 cases of Spanish influenza in Germany and at least 25,000 in Berlin alone. All the hospitals are filled with cases of this malady and all the doctors and nurses are down with it. It is reported also that Austria-Hungary is suffering from an epidemic of typhus, and that influenza has appeared in Budapest and in Danzig.

Start Work on County Tuberculosis Hospitals.—County tuberculosis hospitals are in the process of construction in Broome, Rockland, and Nassau counties, New York. The contracts for the Broome County institution total $117,233. The hospital is located several miles from Binghamton and is to have seventy-five beds. The Rockland County Hospital will be located near New City and is to cost approximately $90,000. The Nassau County Hospital is being erected on a 97-acre site near Farmingdale and will cost about $108,259.

School Kept Open During Measles Outbreak.—The June issue of the Bulletin of the New York State Health Department states that in controlling an outbreak of measles it is not always advisable to close the schools. When measles appeared in

Kingston the sanitary supervisor made a survey and found that there had been 355 cases of measles reported to the city health officer. A survey of the schools showed that 83 per cent. of the children in the parochial schools and 79 per cent. of the children in the public schools were immune to measles. The sanitary supervisor advised keeping the school in session as the children who were susceptible could be easily watched. Just as soon as a child exhibited signs of measles he was sent home. By daily visits to the schools the school physician was able to detect and control the beginning cases.

Commissioner Copeland Exonerates Dr. Brown.—At a hearing on July 5, Dr. Lucius P. Brown, director of the Bureau of Food and Drugs, defended himself against the charges brought against him by Mayor Hylan and ex-Civil Service Commissioner McBride. Dr. Brown produced evidence showing that the charges against him were false. At the end of the hearing Dr. Copeland commended Dr. Brown and admitted that the results of his work were of value to the city and that the honesty and integrity of Dr. Brown were in no way in question.

More Cities to Have Tuberculosis Dispensaries.—Through the cooperation of the State Charities Aid Association, which has been assisting local public and private tuberculosis organizations to establish dispensaries for medical oversight, assistance, and sanitary supervision of tuberculous soldiers rejected from military service, arrangements have been made which assure the opening of such dispensaries in Hudson, Newburgh, Kingston, Binghamton, Auburn, and Mount Vernon within a month. Plans have also been perfected for the reopening of dispensaries in Cohoes and Little Falls. Approximately $2,500 a year is required to secure a medical and nursing staff and to equip and operate a dispensary in the smaller cities of the State. In a series of villages and towns in Westchester County arrangements are under way for occasional clinic service to be given by tuberculosis specialists of New York.

A Child Welfare Station in Manufacturing Industry.—At the suggestion of the State Department of Health, through its Division of Child Hygiene, the Endicott-Johnson Company of Endicott has established in its plant a Child Welfare Station, where the children of all persons employed by this company are cared for medically. Ample provision has also been made for the proper education of expectant mothers in matters pertaining to their personal health and hygiene and for the better care of the nursing mother and the new-born babe.

Charitable Gifts and Bequests.—The will of Meyer H. Lehman bequeathes $25,000 to Mount Sinai Hospital, New York, and $10,000 to the United Hebrew Charities.

The proceeds of a base ball game and a circus for the benefit of the Saranac Lake General Hospital have netted that institution over $1,000.

By the will of the late Gustavus A. Müller of Philadelphia bequests of $500 each are made to the Lankenau and the St. Agnes Hospital.

By the will of the late Mary Anspach Ashmead of Philadelphia trust funds are set aside yielding incomes as follows: Philadelphia Home for Incurables $10,000, Methodist Episcopal Hospital $5,000, Hospital of the University of Pennsylvania $3,000.

By the will of the late Dr. Gwilym G. Davis of Philadelphia the sum of $3,000 is bequeathed to the Hospital of the University of Pennsylvania for the Children's Orthopedic Ward, and the sum of $500 to the College of Physicians of Philadelphia.

Under the will of Dr. William Mecklenburg Polk, Cornell University receives $5,000 to continue the John Metcalf Polk scholarship in the Medical School.

The Women's Hospital and the New York Dispensary, each receive $10,000 under the will of Miss Cornelius A. Beekman.

Dr. Jay Frank Schamberg has been elected Professor of Dermatology and Syphilology at Jefferson Medical College in succession to Dr. Henry W. Stelwagon resigned.

Dr. Martin E. Rehfuss has been elected Associate in Medicine at the Jefferson Medical College, Philadelphia.

Dr. William C. Woodward, health officer of the District of Columbia, has been appointed Health Commissioner of Boston.

Dr. R. Morton Smith of Riverport, R. I., has been elected President of the State Board of Health of Rhode Island.

Dr. Harry S. Bernton has resigned his position as Pathologist of the State of Rhode Island in order to accept the position of Chief of the Bureau of Preventable Diseases and Director of the Biological Laboratories of the District of Columbia.

Dr. Charles H. Weinsberg of St. Louis, who was tried on the charge of violation of the espionage act, has been acquitted by the Federal courts.

Positions Open to Physicians.—The Civil Service Commission of the State of New York announces that there is a vacancy in the position of Medical Officer and Inspector, Department of Health Officer, Port of New York. The salary is $1,200 a year. The position of Resident Physician, State Training School for Girls, Hudson, is open to women physicians and carries a salary of $1,800 a year. No written examinations will be required, but applicants will be rated upon education, training, experience, etc. Applications must be in the hands of the Civil Service Commissioners at Albany by July 24, 1918.

New Hospital for the Bronx.—The Bronx Hospital Association has acquired a new hospital which is to have a children's ward and a dispensary. Property has been purchased at Fulton Avenue and 139th Street for a little more than $110,000, known as the Eichlen estate, and the Eichlen mansion will be remodeled to serve as a hospital building. A campaign to raise $35,000 with which to alter and equip the building has been started. Dr. Alexander Goldman is president of the hospital association.

Physicians Raise Fees.—A number of East Baltimore physicians met recently and formed an organization for social and professional advancement. One of the first things they did was to decide upon a new schedule of fees, namely, office calls $1, outside calls $2, and night calls $3, and the lowest fee for obstetrical cases $25.

Italian Hospital Needs Funds.—A campaign to raise $100,000 is being carried on by those interested in the Italian Hospital, New York. This amount of money is urgently needed to keep the hospital going until the end of the year.

Medical Society Elections.—The MASSACHUSETTS MEDICAL SOCIETY, at its 137th annual meeting, on June 18, elected the following officers for the ensuing year: *President,* Dr. Samuel B. Woodward of Worcester; *Vice-President,* Dr. George P. Twitchell of Greenfield; *Secretary,* Dr. Walter L. Burrage of Jamaica Plains; *Treasurer,* Dr. Arthur K. Stone of Framingham Center; *Librarian,* Dr. Edwin H. Brigham of Boston.

The MEDICAL SOCIETY OF THE STATE OF NEW JERSEY, at its 152d annual meeting, held at Spring Lake on June 25 and 26, elected the following officers: *President,* Dr. Thomas W. Harvey of Orange; *First Vice-President,* Dr. Gordon K. Dickinson of Jersey City; *Second Vice-President,* Dr. Philander A. Harris of Paterson; *Third Vice-President,* Dr. Henry B. Costill of Trenton; *Secretary,* Dr. Thomas N. Gray of East Orange; *Corresponding Secretary,* Dr. Harry A. Stout of Wenonah; *Treasurer,* Dr. Archibald Mercer of Newark; *Editor of Journal,* Dr. David E. English of New Brunswick.

The AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION, at its thirty-fifth annual meeting, held in Boston, June 5 and 6, elected the following officers: *President,* Dr. Guy Hinsdale of Hot Springs, Va.; *Vice-Presidents,* Dr. Joseph H. Pratt of Boston and Dr. Hugh M. Kinghorn of Saranac Lake, N. Y.; *Secretary-Treasurer,* Dr. Arthur K. Stone of Boston; *Recording Secretary,* Dr. William D. Robinson of Philadelphia.

The WOONSOCKET DISTRICT MEDICAL SOCIETY, at its meeting in Providence, R. I., on June 22, elected the following officers: *President,* Dr. Edward L. Meyers; *First Vice-President,* Dr. James A. King; *Second Vice-President,* Dr. Robert G. Reed; *Secretary,* Dr. E. F. Cameron of Slatersville; *Treasurer,* Dr. A. Constantineau.

Obituary Notes.—Dr. CHARLES ALFRED TYRRELL, a graduate of the New York Eclectic Medical College, in 1900, died at his home in New York on July 2, aged 72 years.

Dr. WILLIAM DILLON died at his home in Brooklyn on June 26, aged 61 years. He was a graduate of the Royal College of Surgeons, Dublin, in 1884, and of the Royal College of Pharmacy of Ireland in 1885, and practiced medicine in London before coming to this country.

Dr. SIMEON LESLIE WEST died at Philadelphia on June 22 at the age of 73 years. He was graduated from Jefferson Medical College in the class of 1868. He was a member of the Medico-Legal Society of Philadelphia, the Philadelphia County Medical Society, and the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. JOHN SHRIVER WENTZ died at Philadelphia on July 1 at the age of 81 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1858. He served as a surgeon in the United States Army during the Civil War.

Dr. EDWIN C. COWPERTHWAITE, a graduate of the Hahnemann Hospital and Medical College, in 1895, died at his home in Philadelphia on June 11, aged 45 years.

Dr. ROBERT SIMPSON died at Philadelphia on June 19 at the age of 74 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1874.

Dr. CHARLES C. HENDRICK, a graduate of the New York Homeopathic Medical College in 1894, and for many years a resident of New York City, died in Plainfield, N. J., on June 26, aged 55 years.

Dr. WILLIAM T. MCAVOY, a graduate of the Bennett Medical College, Chicago, in 1913, and formerly a member of the Swedish Hospital, Brooklyn, died at his home in that city on June 21, aged 37 years.

Correspondence.

INTRATRACHEAL ANESTHESIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In my address on "Thoracic Surgery" which appeared in the issue of the MEDICAL RECORD for July 6, I discuss Dr. Bevan's statement with regard to intratracheal anesthesia. I sent this to Dr. Bevan on May 31 for an expression of opinion. Unfortunately he did not receive my letter until June 27, but in a letter dated June 28 Dr. Bevan writes: "I should be very glad to have you make the following statement from me in your article provided you quote in full in regard to intratracheal anesthesia." This letter came too late to permit the incorporation of Dr. Bevan's statement in my article. The statement is as follows: "I have not personally employed the intratracheal method of Meltzer and Auer, nor have I had any personal experience with a number of other methods which I have discussed in this paper on the 'Choice and Technique of the Anesthetic.' For instance, I have not produced complete anesthesia with scopolamine and morphine alone; I have never employed spinal anesthesia in my work; I have never blocked the Gasserian ganglion; I have never employed the intravenous anesthesia with ether, nor intrarectal anesthesia with ether, nor the so-called 'anoci association.' The statements which I have made in regard to these various methods with which I have had no personal experience are made from a study of the literature, from observation of the work seen in the hands of other men, and from an attempt logically and judiciously to estimate the relative values."

One who read my address and now reads Dr. Bevan's statement will judge for himself whether the position I took requires any change.

S. J. MELTZER, M.D.

NEW YORK.

MEDICAL WEEK IN CANADA.

(From a Special Correspondent.)

HAMILTON, June [illegible]

THE thirty-eighth annual meeting of the Ontario Medical Association began its sessions in Hamilton on May 30. Among the papers read at the morning session was one by Dr. W. Gordon Lyle of New York, with reference to modern methods in the diagnosis of nephritis. Charts of cases of patients who had been studied for renal function were presented, and the value and significance of blood analysis and functional tests in the diagnosis of early

nephritis were discussed. The findings in several hundred cases with special reference to the nitrogen partition of the non-protein nitrogen residue of blood were presented, and the phenolsulphonephthalein test and nephritis test meal were described.

Dr. J. Chandler Walker of Boston, Mass., read a paper in which he dealt with the clinical study and treatment of bronchial asthma. The importance of a careful history of bronchial asthma was emphasized, and sensitization and the treatment of sensitive cases were discussed. Walker did not seem to think that a neurotic temperament bore any definite relation to the causation of bronchial asthma. He laid a considerable amount of these upon the influence that the protein of food and the protein of pollen exerted upon the production of the condition, and pointed out that judicious dieting was of great service both in the prevention and treatment of bronchial asthma. The treatment of non-sensitive cases was discussed and a clinical classification of bronchial asthma and a discussion of such classification was presented.

A paper was given by Dr. Alan Brown and George Smith of Toronto, in which the autoserum treatment of chorea was dealt with. As for the causation of chorea, attention was directed to the fact that a large number of observers believed that chorea was a manifestation of scarlet fever. Autoserum treatment of this condition was first introduced by Dr. Goodman of New York. Brown and Smith had developed three modifications. A detailed report of technic, and results obtained, was presented, and a description was given of the withdrawal of blood from the patient, separating the serum from the blood and its injection into the patient's spinal canal.

In the section in surgery, on the morning of May 30, Prof. Jasper Halpenny of Winnipeg discussed the methods pursued in the training of the surgeon at the present time. He was extremely critical of many of these methods, and quoted Rutherford Morison in support of his contention that the training of the surgeon was not conducted on high lines. However, while Halpenny's criticisms were destructive his suggestions in the way of reform were, in a high degree, constructive. He pointed out the best way of connecting the training-interneship, assistantship, post-graduate work, and the visiting of other clinics. In fact, he indicated the measures which in his opinion would best tend to train the surgeon in the most thorough and effective manner.

Radical operations for cancer of the breast were considered by Dr. D. Guthrie of Sayre, Pa. The history of the development of the operation for breast cancer was given, and the comparative merits and distinctive features of these were discussed at some length. The work of Von Volkmann-Heindenhain with respect to cancer of the breast was gone over and the Meyer, the Halsted, the Warren, the Jackson and the Rodman operations were critically dealt with, and the surgical principles involved therein discussed. Guthrie held that the methods of operating for cancer of the breast subsequent to the introduction by Meyer of his method were all modifications of the Meyer method. In the discussion that followed the reading of this paper Dr. Coborn suggested that it would be in the best interests of all concerned if the operation for cancer of the breast could be standardized. Each great surgeon had his own way of operating, and this tended to confuse the student. If the best features of the best-known modes of operating for cancer of the breast could be standardized it would not only make the operation simpler but would facilitate matters for the student and would be better for the patient. The point was emphasized that especial attention must be paid to the lymphatics in cancer operations. The method of fulguration after operation for cancer, introduced by Keating-Hart, was referred to favorably. The good results obtained from fulguration by Dr. William Seaman Bainbridge of New York were alluded to as conspicuous examples of the value of the method in the treatment of cancer. Dr. Beal of London thought there was no need to attempt to standardize an operation for cancer of the breast. The essential methods of procedure were alike in all, and the slight modifications introduced by different surgeons mattered but little.

The toxemia of eclampsia was discussed by Dr. K. C. McIlwraith of Toronto. There was a toxemia peculiar to pregnancy, usually of slow development, and in some degree controllable. The controllable factors were diet, eliminations, chill, neurotic factors. The essence of treatment was the measure of toxicity which would show when delay was possible and when action was imperative.

At the general sessions on the afternoon of May 30 the addresses, on obstetrics, on pediatrics, and on medicine were given. The address on obstetrics, which was entitled "Methods and Operations for Reducing Fetal Mortality, With Special reference to the Newer Methods of Cæsarean Section," was delivered by Dr. Joseph De Lee of Chicago. He gave a history of the various methods by which women were delivered in ancient times, and a long and interesting account of the evolution and development of the operation for Cæsarean section. The indications for the operation were given in full detail, and it was stated that there were two operations in common use nowadays, the classical operation and the cervical. De Lee advocated the cervical operation for cesarean section rather than what is known as the classical, because convalescence was much smoother.

The address on pediatrics, the title of which was "Asthma in Infancy and Childhood," was given by Dr. Isaac A. Abt of Chicago, Ill. Dr. Abt said in part that it must be borne in mind that infantile asthma differed in type from the form of the disease which occurred in the adult. Asthma in children was more prevalent among the rich than among those in less prosperous circumstances. Seasons had a good deal of effect on the incidence of infantile asthma. Locality had a curious effect on its incidence. Some young children got rid of it in a dry climate, others in a moist climate. The affection was very capricious. It might occur in one room in a house while in the remaining rooms no symptoms of asthma presented themselves, so that really locality exercised no particular influence on its causation. The hypotheses as to its origin were many and various. It had been attributed to bacteria or toxins. Asthma might be the expression of an anaphylaxis, but there was a lack of proof with

regard to this theory. It might be said, however, that anaphylaxis in infants and children was sometimes produced by the ingestion of protein. Injection of a small portion of albumen of egg would produce asthma in a certain child. Pollens and horsehair would produce asthma in some children. Asthma in infants and children has been ascribed to an exudative diathesis. It was said to have a connection with eczema, urticaria, adenoids, etc. Diet certainly played a part in the treatment. Abt thought that the hypothesis as to asthma in the young being due to an exudative diathesis was purely speculative. Bronchial tetany had a closer relationship to asthma than bronchopneumonia. Nasal lesions might bring on an asthmatic attack. Asthma occurred at almost any age in children, and began with marked bronchitis. So far as therapeutic treatment was concerned, calcium chloride had a good effect on asthma. Respiratory exercises might be recommended for older children who suffered from asthma.

The address in medicine, "On the Significance of Heart Murmurs Found in Examination of Candidates for Military Service," was given by Dr. Lewellyn F. Barker of Baltimore, Md. Dr. Barker said, in part, that attention at the present time was focused upon the hearts of recruits. From 1886 great progress had been made in knowledge regarding the heart. The mechanical means for gauging the heart's action had made possible this advance. Dr. Barker pointed out that owing to improved methods of treatment a large proportion of men with heart murmurs, and at the present time not fit for active service, would be rendered wholly or partly fit. Reference was made to the fact that the Central Powers were sending out men with heart affections. The modes of differentiating between organic or functional heart murmurs were described, and it was shown that while some men with heart murmurs should be totally exempted others with murmurs were just as fit to carry on as if no murmurs were apparent.

In the section in medicine of the Canadian Medical Congress, on the morning of May 31, Dr. Beatrice M. Hinkle read a paper discussing the psychoanalysis of the moral conflict in functional neurosis. The dictum of Jung that moral conflict is found to be the basis of every neurosis was referred to, and it was pointed out that Freud's psychoanalysis was the first attempt of medical science to find in the psyche the cause of neurotic conditions. Dr. Hinkle covered practically the entire ground alluded to in the title of her paper, paying particular attention to Freud's theories of repression and resistance, transference, infantile sexuality, dream interpretation, and the technique of psychoanalysis.

In the section on surgery, Capt. George Ewart Wilson, C. A. M. C., of Toronto, read a paper dealing with the treatment of compound fracture of the humerus. Attention was drawn to the unsatisfactory methods at present taught for treating compound fractures of the humerus. A full description was given of a splint invented by the author which allows of the suitable placing of fragments, proper extension and changing of dressings without removal of splint.

Another paper was read by Dr. E. J. McGuire of Buffalo on surgery of the colon. The author animadverted somewhat on Lane's theories and surgical procedures with respect to intestinal stasis. He said, however, that his teaching should not be wholly discarded, as there was contained therein some real element of truth. Notwithstanding, surgery of the large intestine must be limited, with few exceptions, to cases showing definite evidence of obstruction. Ileosigmoidostomy should not be done as an operation of election, resection being the ideal procedure. As a matter of fact, according to McGuire, Lane had discarded sigmoidostomy in favor of resection. Moreover, side-to-side anastomoses were unsatisfactory, as demonstrated by the frequency with which diverticula developed in the blind end. End-to-end anastomosis gave the most satisfactory results.

Among the papers read in the section in obstetrics, on the morning of May 31, was one by Dr. B. P. Watson of Toronto, entitled "The Technique of Operations for the Repair of the Perineum." In it were discussed the value of immediate repair after delivery, and especially the importance of closure of tear in vaginal mucosa and coaptation of musculofacial layers. The secondary operation was described and the need for the thorough exposure and union of separated levator ani muscles and of the torn triangular ligament was emphasized. The paper was illustrated by lantern slides.

Dr. Joseph C. Beck of Chicago gave a lecture on the teaching of plastic surgery of the head and neck. The importance of teaching plastic surgery was dwelt upon and the types of injuries in the present war were described, as well as the varieties of injuries of the internal ear and of the external ear and their plastic reconstruction. A description was also given of the plastic reconstruction indicated when a great part of the nose was lost, with special reference to the use of the superior maxilla; also temporary and permanent resection for bullets in the retromaxillary fossa and the plastic reconstruction of the larynx. The question of cartilage and bone transplantation was entered into, and nerve plastic procedures with special reference to the facial-hypoglossal and facial-spinal accessory anastomosis were considered. Laryngeal plastic operations, and cosmetic means for restoring features to apparently normal conditions were discussed at considerable length.

On the afternoon of May 31 the general session was devoted to a symposium on Intracranial Pressure. Dr. J. J. R. Macleod of Cleveland, Ohio, gave an address on the physiology of the subject. He said there could be no expansion through intracranial pressure unless there were means for such expansion. Venous pressure was more important than the work done by the arteries, but at the same time their action was interdependent. When the heart failed cerebral pressure was raised and arterial fell. As for the cerebrospinal fluid, it only acted as a lubricant, in the same way as the synoidal gland acted. The apparent absence of vasomotor nerve fibers was referred to and the consequent dependence of the blood supply upon changes occurring in other parts of the vascular system. He said that Leonard Hill of London was the greatest authority on intracranial pressure, and had devised the only instrument to measure correctly intracranial pressure. Macleod asked why a tumor had caused intra-

cranial pressure, and answered that it did not. It caused local cerebral anemia and increased intracranial pressure by producing anemia.

Medicine and surgery in their relation to intracranial pressure were discussed by Drs. W. P. Hamilton and A. E. Garrow of Montreal respectively. Both speakers necessarily covered a good deal of the same ground as Dr. Macleod. Dr. Garrow described the various surgical methods for removing the effects of intracranial pressure caused either by injury or disease.

Dr. H. Beaumont Small of Ottawa was elected *President* of the association. The *Vice-Presidents* are the presidents of affiliated societies and the presidents of provincial societies *ex-officio*. *Secretary-Treasurer*, Dr. W. W. Francis, on active service. *Acting Secretary*, Dr. J. W. Scane of Montreal.

The Canadian Medical Protective Association elected the following officers: Dr. R. W. Powell of Ottawa, *President;* Dr. J. A. Camarand of Sherbrooke, Quebec, *Vice-President;* and Dr. J. Fenton Angus of Ottawa, *Secretary-Treasurer*.

The Ontario Medical Association elected the following officers: *President*, Dr. J. S. Cameron, Toronto; *First Vice-President*, Dr. J. H. Mullen, Hamilton; *Second Vice-President*, Dr. J. F. Argue, Ottawa; *Honorary Treasurer*, Dr. Gordon Bates, Toronto; *Honorary Secretary*, Dr. T. C. Rontley, Hamilton; *Assistant Secretary*, Dr. F. C. Harrison, Toronto.

OUR LONDON LETTER.

(From Our Own Correspondent)

CONCERTED ACTION UPON FOOD QUESTIONS—FEES FOR MEDICAL ATTENDANCE ON MEDICAL MEN—THE COMING MINISTRY OF HEALTH—EXEMPTION OF MEDICAL MEN FROM MILITARY SERVICE—CARE OF THE TUBERCULOUS SOLDIER—THE LATE DR. ROBERT FARQUHARSON.

LONDON, June 13, 1918

It is as important that the Allied nations should come to some complete mutual understanding upon food questions as upon questions of munitions, transport, medical care, and even military strategy. Concerted action in every department of life should be the motto of the Allies, and medical men in each of the Allied nations have been prompt to point out that as regards food such action would have enormous value in conserving the strength and mansupply of the belligerents for the right. It may be remembered that an Inter-Allied Conference was held in Paris late last year at which an International Scientific Commission was instituted, whose function should be to meet at stated intervals for the consideration of any food problems that were presenting themselves. The periodical sessions were to be of a strictly scientific character, and it was understood that their outcome would be communicated in the form of expert advice to the various governments. The International Scientific Commission has a strong membership, as the following names show: *France*, Professors M. Gley and J. P. Langlois; *United States*, Professors R. H. Chittenden and Graham Lusk—these four men by themselves constitute a powerful and learned committee on all food questions; *United Kingdom*, Professor E. H. Starling, our most learned practical physiologist, and Professor T. B. Wood, Professor of Agriculture in the University of Cambridge; *Italy*, Professors Pagliani and Botazzi; and *Belgium*, the Home Secretary, Professor Hulot. Two sessions of the Commission have now been held. The first in Paris last March cleared the ground by coming to certain conclusions in respect of minimum food requirements; the second, held in Rome in April and May, considered questions of general interest to the Allied populations, the conclusions thereon being now in the press.

A recent action in the High Courts of Justice has given a sort of legal standing to what hitherto has been merely a convention, though a universal one, among British medical men. In the case in question, a physician, who was in attendance on the wife of another physician, sued his patient for medical services rendered, the action, primarily against the wife, taking effect against the husband, who was the legal defendant. The case of the plaintiff was that his fees were to be paid, not by the husband, but by the patient's stepfather, the motive of the action being to speed up the stepfather, rather than to mulct the husband. As the action, however, occurred in the courts, it was brought by a plaintiff doctor against a defendant doctor, for money owing in respect of medical services, and, as such, was a novelty in the courts, because among doctors such matters when in dispute are settled outside the law. The universal convention in this country is that doctors render gratuitous medical services to other doctors and to their immediate family and dependents. Exceptions occur where an arrangement to the contrary is made on the ground either that the medical service required would be unusually onerous, or that the medical man who is being benefited is manifestly a richer man than he whose services are demanded. No such mutual understanding had been reached in the case in question. Certain pecuniary help was received from the stepfather, whereby certain fees were paid to the plaintiff, but the other money was paid by the defendant out of his own pocket, believing himself to be making a complete settlement in so paying. The action was for a balance alleged to be still due and unpaid. Judgment was given for the defendant, the position being recognized that the account should not have been rendered by the plaintiff; but on the suggestion of the judge, the amount of payment still due, if any, to the plaintiff, further than that which he had already received, was referred to Sir Henry Morris as arbitrator. No better arbitrator could have been found. Sir Henry Morris, lately President of the Royal College of Surgeons of England, which body he represented for years on the General Medical Council, is also Treasurer of Epsom College, a medical foundation, and has all his life been in the closest possible touch with questions affecting medical procedure and standards of conduct. Sir Henry Morris interviewed both the plaintiff and the defendant, and came to the decision, which has now been published, that the plaintiff had no grounds for thinking that he had not been fairly treated by his patient or by her husband. The statements made to him by the two parties showed that the plaintiff had been remunerated for several years at a rate varying from £100 to £180 per annum, in

view of which Sir Henry Morris considered that the plaintiff had not any moral claim to further payment.

The discussion at the Royal Society of Medicine on the professional problems arising out of the impending establishment of a Ministry of Health was continued this week and last week, the important speakers being Sir William Osler, Sir Watson Cheyne, Dr. G. E. Haslip (Treasurer of the British Medical Association), Dr. Smith Whitaker (Deputy Chairman of the National Insurance Commission), Dr. C. E. Buttar (Chairman of the Executive of the Central Medical War Committee), Professor Benjamin Moore, and Surgen General Sir Bertrand Dawson. As the result of a free interchange of views the meeting decided unanimously that a committee of the Society should be appointed to hold a watching brief for medical interests. This resolution has been transmitted to the governing body of the Society, and is sure to receive effect. Such a committee may prove of real value to the medical profession when the bill constituting a Ministry of Health comes before Parliament.

The Central Medical War Committee has issued this week to the medical profession, through its local bodies, the Local Medical War Committees, a memorandum dealing with the duties of those bodies, especially in making the new calls on the medical profession as little onerous as possible. The position of the medical man who makes no claim for exemption is set out in some detail. He is given an exemption which holds good so long as he is not offered a commission, with the proviso that he will undertake such professional work as the Director General of National Service may offer him—"standard exemption." The position works out as follows and displays considerable ingenuity on the part both of military and civil officialdom: The Local Arrangements Sub-Committees of the Central Medical War Committee will consider from what areas, having regard to their population, medical men can be spared, either for the army or for districts less fortunately provided with medical service; in those areas where a call is made the doctors will be examined physically by boards appointed by the Ministry of National Service: they may be granted a "standard exemption," but those who wish for a different form, *i.e.* a more complete form of exemption, will be given a hearing. It is understood that men will not be moved capriciously from one district to another by the Ministry of National Service, and that the desire is to disturb as few practitioners as possible, it being felt that their best work can probably be done in the familiar environment. The choice of the authorities in allotting work to a man, military or civil, will be determined mainly by his age and his health. These are the promises, and they will be kept if only because to break them would be too silly.

The tuberculous soldier is already proving one of the most difficult problems of this country, a problem whose solution will not be arrived at until many years after the nations have laid down their arms. By the end of 1917 20,000 men at least had been invalided from the British Army through tuberculosis, and it is felt that on all grounds careful watch should be kept, first in the recruiting stations to see that infected subjects are not admitted to the army, and, secondly, in the ranks to see that the cases which occur are taken in hand early. Both in Italy and France tuberculosis as a cause of invaliding from the army has become a serious matter, while Italy has recently received large batches of interned prisoners from Austria among whom tuberculosis is very prevalent. In fact it seems quite undoubted that the incidence of tuberculosis on the central empires is much heavier than it is on the Allies. In France the situation is being dealt with by local committees in each department, who inquire into all cases of tuberculosis among service men, and, while obtaining medical treatment for them, take steps also to insure their civil employment when they are restored to health. We have today greatly increased provision for the treatment of tuberculosis, both medical and surgical, in existing institutions, while new ones are being built especially for the purpose; also five Farm Training Colonies have been started for tuberculosis patients, one near Bournemouth, one near Liverpool, one near Hull, one near Cambridge, and one near Edinburgh.

The ominous position of tuberculosis in Ireland, where the stress of war has not yet been felt, leads directly to the observation that the connection between a certain increase in tuberculosis rates which have occurred locally and the returned soldier is not so direct as has been supposed. The death rate for tuberculosis has risen for example in Belfast, where the civilian population at the present moment probably enjoys higher wages and better food than it has ever enjoyed; and simultaneously with this we find that in some crowded British areas the incidence of tuberculosis is lower than usual and its mortality correspondingly abated. In Dublin, where the artisan class is not so prosperous as in Belfast and where there is always a great deal of poverty, the City Corporation should have ample funds to deal with tuberculous cases, and there is no reason why the tuberculosis rates should be connected directly with the war. There is something about the public health aspects of tuberculosis which everlastingly seems to invite confusion of mind, and it would almost seem as if some public health authorities are prepared to attribute any rise in tuberculosis to the war instead of investigating other circumstances, any of which might equally well or ill be the determining one in a particular locality. One point here, however, must be remembered—the public health departments of some localities have been depleted with the only result that organized tuberculosis work has suffered. As a rule, however, the local Government Board has exercised its power to obtain exemption from military service of all medical officers the cessation of whose work might be attended with widespread mischief to the population.

The death is announced this week at the age of 82 of the Laird of Finzean, the Right Honorable Robert Farquharson, who was for many years Member of Parliament for an Aberdeen constituency, and also while in the House of Commons was the untiring advocate of medical reform. He enjoyed the rare distinction for a medical man of

being a Privy Councillor, and before succeeding to the family estate was one of the surgeons to the Coldstream Guards.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

CHILDRENS' DISPENSARY AT MARSEILLES—LOSSES IN THE ARMY MEDICAL CORPS—THE RED CROSS AND THE FRENCH SCHOOLS—NEW FACES FOR THE DISFIGURED—NEW MEMBERSHIP IN THE ACADEMY.

PARIS, June 4, 1918.

MORE than 200 mothers brought their children to the opening session of the Red Cross children's dispensary at Marseilles this week. Aided by five nurses, Dr. Oscar H. Sellenings, of the Children's Bureau, examined child after child and gave advice on medical care to their mothers, but more children came than he could possibly attend to in a single afternoon. The dispensary is the first Red Cross institution to open in Marseilles, where Dr. William Palmer Lucas, chief of the Children's Bureau, has arranged for a hospital and a child-welfare exhibit as well. The Red Cross work at Marseilles is done in close cooperation with a large group of French societies which have united to form a "section of defense against infant mortality of the central office of the œuvres of Marseilles." Among the œuvres which are co-operating with the Red Cross are the "Abri Maternal," with which Dr. d'Astros is associated; the "Protection Maternelle d'entr'aide Féminine," the "Pouponnière du Prado," the "Charité Saint-Joseph," and so on.

Before the war some 80,000 babies died annually in France; investigation has shown the condition is even more serious now. Women's work in the munition factories, although a national necessity, has been in fact jeopardizing the future to save the present. It has tended to lower the national birth rate which was already too low. In conjunction with the Ligue contre la Mortalité Infantile and the Federal Government, the Children's Bureau of the American Red Cross has worked out a definite program of preventive measures. Whatever clinics for nursing mothers exist, or have existed, the Red Cross aids them or aids them to reopen them. Since most of the women available for health visitors or nurses have been drawn into the military hospitals, the Red Cross is aiding to create short, intensive courses for women who have had some hospital training to make them effective health visitors. Such courses have already been established at Paris, Lyons, Marseilles, and Bordeaux. The opening of the dispensary at Marseilles and the establishment of the training courses for health nurses there, in intimate cooperation with French societies which have long been at work, are the first steps in the preventive campaign in the commercial capital of Southern France.

We of the French Medical Corps have known that the losses by killed, wounded, and captured of our members have been very heavy, but no lists are printed and no information, other than of individual cases, comes to our knowledge, so we are in complete ignorance of the totals. I do know that last spring, a year ago, 600 French army doctors, prisoners in Germany, were returned to France, via Switzerland. Some general idea, however, can be gained by the grave sacrifices made by these devoted non-combatants by certain information given in a recent publication by Lord Northcliffe respecting the losses in June, July, and August during the battle of the Somme in 1916. Doctors killed, 53; doctors wounded, 208; doctors missing, 4; medical assistants killed, 260; medical assistants wounded, 1212; medical assistants missing, 3.

School has reopened at Cuffies. It is just one of dozens of little villages in the liberated districts where the schools have been closed for nearly four years and are just beginning to reopen. At Cuffies the French Government put up a rough wooden barrack to replace the brick building smashed by the Germans, and the Red Cross answered a hurried call for chairs. Cuffies is one of a number of towns where the Red Cross has helped reopen schools. Pommiers is another little town in the Aisne where school has started again. It is the only town with a school for miles around, and the children walk in from all the surrounding villages. This made it necessary to give them their déjeuner at school, and the Red Cross answered another emergency call, supplying vermicelli, chocolate, and condensed milk for the schoolchildren.

Rebuilding houses, making it possible to reopen schools and to resume farm life in a region where every farm machine and every cart wheel has been destroyed, is all part of the Red Cross work in the Somme, Oise, and Aisne. The delegate for the Aisne has just reported the arrival of six cartloads of supplies, largely wheelbarrows, spades, pitchforks, and shovels. Restoring industry is another part of the Red Cross program in the reviving regions. Wherever possible, local factories are encouraged to resume production—which helps them and saves transportatien. The chairs sent to the Cuffies schoolhouse were the first products of a factory which has stood idle since the war began.

Many of these towns have difficulty in securing adequate food supplies. Cuffies is typical of many others. The red Cross recently sent a camionload of foodstuffs to Cuffies and unloaded it into the cellar of one of the townspeople, whence it was distributed by the mayor. There was only one man to do the unloading, but a score of the school children came to his aid, clambering into the auto and handing things down, with a ride in the camion to the last house in Cuffies as their ample reward and salary.

The Bureau for the Mutilés under the direction of Miss Grace Harper of the American Red Cross is developing its reeducational work under three heads. The farm that is being put in order preparatory to receiving the students of agriculture is probably the department that will be the most important. The second branch includes the propaganda that is to be carried out by means of lectures and cinematograph entertainments to encourage the mutilated soldiers of France in attending the schools. The third branch is proving of great value in the work of making masks for disfigured faces. Mrs. Maynard Ladd, the American sculptor, first undertook this work and has made such a success of it that two other women sculptors have been employed to assist Mrs. Ladd. Mlle. Jeanne Poupelet

is now engaged in making the galvanic copper copper masks and another sculptor from America will also assist in developing this work.

The Red Cross furnishes the funds for making the masks at a cost of about 100 francs each. The surgeons of the Val-de-Grâce hospital have recognized the work so successfully that Mrs. Ladd has been given carte blanche in fitting the mutilated soldiers of the hospital with these remarkably life-like faces.

The Academy of Medicine has just made a new ruling regarding "Académiciens libres," limited to ten members who, not having the degree of doctor, are recognized because of some notable service rendered to the cause of medicine. Heretofore these members were required to post their candidature, but by the new ruling they may be named by a fixed committee in the Academy and elected by a two-thirds vote at a regular meeting.

5. An Acute Febrile Entity with Vomiting, Somnolence, and Acetone.—Harry Lowenburg describes a condition occurring in infants and young children and exhibiting with marked uniformity the following symptoms: Fever, forceful vomiting, somnolence, and the odor of acetone upon the breath. The onset is abrupt and is accompanied by fever reaching 101° to 104° F., which lasts for a few days and falls by rapid lysis. Acetonuria is present and there is a faint trace of albumin. The drowsiness is persistent and amounts to a mild stupor. The pupils as well as the deep and superficial reflexes are normal, muscular rigidity is absent, and the child permits himself to be moved about without protest. The pulse rate increases with the rise in temperature, but does not partake of the nature of the slow, full, irregular pulse of meningitis—an important point of differentiation. No abnormality in the blood was noted in the author's cases, but further study on this point is necessary. Catarrh may be present and diarrhea troublesome; cough and varying degrees of bronchial irritation have been noted. The author is unable to classify this entity. He points out that acetone on the breath and the acetonuria may be symptoms of an acute febrile process or, on the other hand, they, with the fever and somnolence, may represent the main and distinctive symptoms of an acute acid intoxication depending up some undetermined etiological factor. Whether or not it is a form of influenza cannot be determined until its bacteriology has been studied. At the bedside the condition must be differentiated from meningitis, pneumonia, appendicitis, typhoid fever, and head injuries. As to prognosis, all the author's patients recovered, although convalescence was stormy in some. One fatal case, however, is reported by Dr. Shmookler, in which the temperature was 107° F. and death occurred from hyperpyrosis. The treatment indicated is a hunger period of 24 hours, calomel administration—1/20 grain every 15 minutes placed dry on the tongue for ten or twenty doses—with counterirritation over the epigastrium to control vomiting, followed by 0.5 ounce of castor oil. After free evacuations small amounts of solids may be permitted, followed by broths and gruels. No milk should be permitted for some days. One or two warm baths daily are of service, and an enema of from 20 to 30 grains of bicarbonate of soda is useful. This remedy may also be given by mouth in doses of 60 to 120 grains in 24 hours. Small doses of aspirin and aconite will control the temperature.

2. Reliability of Ozone in Swimming Pool Disinfection.—Wallace A. Manheimer recommends the use of ozone for swimming pool purification for the following reasons: It is reliable as a disinfectant and, unlike the halogens, its use results in no objectionable odor or taste; it is capable of purifying heavily polluted pool water; it produces no objectionable substances in the water; it improves the appearance and transparency of the water, permitting a longer continued use of the pool, a consequent reduction in the cost of maintenance and a reduction in the hazard of drowning; it is inexpensive in application, costing in the case of a 60,000 gallon pool only from eleven to fifteen cents a day if alternating electric current is available, and where direct current must be converted into alternating current an additional ten to fourteen cents.

1. An Address on Kineplastic Amputations.—Professor V. Putti reviews briefly the fundamental theories of Professor Giuliano Vanghetti's plastic motor flaps and indicates the vast field thrown open to the orthopedic surgeon through the application of these theories, which as yet are little known in France, England, or America, though they have been studied by Austrian and German surgeons. The object of "kinematic amputation" is to utilize the functional resources of the stump so as to convey movement to the artificial limb. The name *kinematic plastics*, or *kineplastics*, has been given by Vanghetti to any kind of bloodless or operative plastics which tend to economize, restore, or substitute muscular masses which can be employed toward imparting direct and voluntary movement to an arti-

ficial limb. The term *kinematisation* is now applied to every kind of kinematic artificial limb and to the active and precocious mobilization of such muscles as are involved in kineplastic operation, while every moving entity obtained kineplastically is caller *plastic-motor* (motor flap). These motor flaps vary as to their number, position, shape, and function, and in order to correspond with the object for which they are made, they must conform to the following requirements: they must possess every requisite for withstanding a firm, resisting, and painless grip, also a traction that may attain a high degree; they must be provided with a sufficient amount of functional muscular tissue to guarantee the accomplishment of the task that will be demanded of them. The muscles must be sought and obtained from among those of which the stump still disposes. Skin flaps, muscular insertions, various bone and tendinous fragments and segments of limbs, which would seem utterly superfluous under ordinary circumstances, must be considered of the greatest value in view of future kineplastics, and even in the first aid dressing station this must be borne in mind by the surgeon. It is evident that the application of kinematization will entail a radical upheaval of all preconceived notions regarding methods of amputation. Although the actual idea was conceived over twenty years ago, kinematisation has only been applied on a large scale since the beginning of the war and it is yet too early to render final judgment. From a consideration of his own cases, however, Professor Putti has come to the following conclusions: (1) The practical results that have been obtained through kinematization have shown that the hopes placed in the principles and methods of the modern theory of motor-flaps are thoroughly justified, and that kineplastics are entitled to be placed among the most brilliant of the discoveries of orthopedic surgery, deserve to be accepted with perfect confidence, and to be tested on a large scale by all those whose aim it is to restore to the disabled man his functional activity. (2) That the preparation of motor flaps is a well-defined surgical act that must be performed in accordance with its own special technique, the methods of which have already stood the test of experience. (3) From a physiological point of view motor flaps are actually capable of giving both the quantity and quality of action determined by the muscular masses that actuate them. Yet, practically considered, motor flaps will be able to yield the full measure of their value only if the artificial limb is perfectly adapted to their shape and their strength. (4) As the principal aim is to attain the vitalization of the artificial limb, it is essential that the surgeon and the mechanic should work in harmony in order to solve satisfactorily this most interesting, if difficult, problem.

2. The Relation Between Heat-Stroke and Malignant Malaria.—Captain C. E. H. Milner suggests that heat-stroke as a clinical entity is non-existent and that it is nothing more than a symptom of malignant tertian malaria. In Mesopotamia during the summer of 1917 there were two formidable heat waves, one in July and the other in August. During the August wave a routine examination of blood film for the presence of malarial parasites was made in heat-stroke cases. In view of the high percentage of such cases in which the *Laverania malariae* was found, an intramuscular injection of 8 or 9 grains of bihydrochloride of quinine was administered, with the result that the mortality, which during July was as high as 25.65 per cent., dropped to 11.76 per cent. in August. This would seem to point to malignant malaria as being the primary cause of hyperpyrexial heat-stroke. Milner points out that it may reasonably be supposed that one of the symptoms of an infection with the parasite of malignant tertian malaria is the intoxication of the heat regulating center, and that once this apparatus is upset the body will assume as nearly as possible the temperature of the atmosphere. Heat stroke does not supervene because sweating ceases, but the patient ceases to perspire because he has got heat-stroke and is suffering from paralysis of the heat regulating center.

6. Post-operative Pulmonary Embolism Due to the Condition of the Blood.—A. Lapthorn Smith points out the value of drinking plenty of water and of frequent movement as preventatives of embolism following operation or confinement. He believes embolism to be due principally to a hyperfibrinous condition of the blood. He therefore makes the following recommendations: (1) Have the full normal proportion of water in the blood before operating. (2) Replace by the rectum the amount of liquid lost by vomiting, catharsis, sweating, hemorrhage, and urine, either during the operation or immediately after it. (3) Encourage the patient to move the lower limbs freely, if not during the first two days, at least during the next ten. (4) Give the patient abundance of water between meals and during the night; it may be hot or cold, sweet, sour, or salty, in the form of lemonade, barley water, weak tea without milk, or beef tea; a jug and drinking cup with spout should be left within reach so that it may be taken when wanted without waiting for the nurse to come. (5) Speedy operating lessens embolism, because it means less hemorrhage, and less sweating and less loss of water from the system. (6) Round-pointed needles with flat eyes are much less likely to cause hemorrhage than ones with cutting edges, and should alone be used in the abdomen.

Berliner klinische Wochenschrift.

Are There Any Other Bacteria Besides the Proteus of the Weil-Felix Type Which Can Be Agglutinated by the Blood of Typhus Patients?—A. Kreuscher, starting with the supposition that the Weil-Felix reaction, specific in typhus fever, does not imply the attributions of a causal part to the Proteus X19, asks himself the question if other bacteria present in the digestive tract of the patients may not likewise be agglutinated by their blood. In point of fact, the writer has been able to cultivate an organism of the pyocyanic group, from the feces of a patient who died from the disease and found that this organism was electively agglutinated with the blood or typhus patients. This property was maintained by the organism down to the 150th generation in cultures. The culture and staining properties of the bacillus were very labile and changed considerably from the effects of laboratory manipulations. Nevertheless, its agglutination by typhus blood remained unchanged. The writer recalls the fact that the X19 of Weil-Felix, offers the same constancy in its biologic characters for the same variations in its bacteriologic characters.

Essays in Prophylaetic Vaccination for Typhus Fever.—P. Neukirch draws conclusions from unfortunate essays undertaken by a physician who was later found to be insane, with a so-called prophylactic injection of defibrinated blood, taken from typhus patients. The result was that those inoculated developed the disease after an incubation period of about twelve days' duration, in all seventy-six cases observed in Anatolia. The mortality was 25 per cent. in young and strong men. The injection did not give rise to any local or general seric phenomena. Neukirch has made essays with a serum derived from typhus cases, prepared by shaking in chloroform, at the dose of 2 c.c. given twice with an interval of from two to three days. Although he is unable to offer exact statistics, the writer was able to note that the subjects who received prophylactic injections were less apt to contract the disease than others. Out of a total of 300 subjects who went to

an infected district and who were certainly bitten by lice, only twelve contracted the disease and none of them died. The writer recommends this procedure especially in cases in which the destruction of lice cannot be realized.

Münchener medizinische Wochenschrift.

Radiological Examination of the Duodenum by the Use of a New Technique of Radioscopy and Radiography.—Chaoul offers the following procedure which consists in radiographing the duodenum after the ingestion of some opaque powder with the patient lying in the right ventrolateral position and exercising a certain amount of pressure with the ampoul and its tube over the part. He thus causes the pyloric portion of the duodenum to become displaced to the right of the spine, while at the same time the transversal portion is compressed between the spine and the photographic plate. After about ten minutes in this position the duodenum will have become filled, when a radiograph can be taken which will indicate the presence of an ulcer with the same precision as that obtained in cases of gastric ulcer. The writer in the present contribution relates the improvements that he has been able to realize in the use of his technique and he says that he has developed it to such an extent that at present he is able to follow on the screen the progressive filling of the duodenum and thus to select the proper moment for taking a permanent radiograph.

Treatment of Erysipelas by Silver Nitrate According to Gangele's Technique.—N. Gondos has tried the treatment advocated by Gangele (reviewed in the MEDICAL RECORD, March 2, 1918) and comes to the conclusion that it is valueless. In no instance could this treatment be regarded as "specific," as is maintained by Gangele.

Deutsche medizinische Wochenschrift.

April 18, 1918.

The Nature and Treatment of Chronic Renal Affections.—F. Volhard accepts the modern conception of ischemia of vascular origin as the explanation of Bright's disease and its manifest symptoms. This ischemia can be demonstrated by examination of the retina and microscopic examination of the skin of the nails (Weiss). The reason for the vascular contraction is as yet not understood, but according to the writer it is a state of angiospasm. Cerebral ischemia and the oedema which results are the causes of the nervous accidents ordinarily termed "uremic." Volhard draws therapeutic consequences from these considerations, particularly a hunger cure of three to five days' duration, followed by the ingestion of 1500 c.c. of liquid, which brings about an upheaval, so to speak, of the disturbed renal junctions. A proper diet should be prescribed to overcome the nitrogenous retention by elimination of meat from the diet, likewise the elimination of salt when edema is present. In the phase of edema arising in Bright's disease fully developed, urea is alone active on the condition that it is exhibited in large doses of 50 to 60 grams, in twenty-four hours.

The Preparation of Antigens for Wassermann's Reaction with Antiformine.—I. Freund, starting from the supposition that the lipoids constitute the active principle of the antigens extracted from the human heart and liver of the syphilitic poetus, the heart and liver of calves, etc., treats these viscera with antiformine which, as is known, dissolves the organized tissue and leaves the active lipoids intact. These lipoids can be taken up by the usual dissolvents and result in the production of more potent antigens than those now generally employed.

A Painful Spot in Gastroptosis.—A. Alexander describes a painful spot which he says is characteristic of gastric ptosis. It is seated below the tip of the sternum and topographically corresponds to the upper portion of the stomach. It is the result of traction on the vagosympathetic plexus from dropping of the stomach.

A Project for Medical Instruction According to a New Plan.—R. Stigler criticises the methods of medical teaching now current almost everywhere, and he quotes Porter and Flexner, the first of whom concludes that German teaching "procures information for the student but no knowledge." Stigler points out the utility for the student to participate in the intellectual work of the professor and this may be attained by a system of lectures.

Infectious Diseases at Belgrade in 1916.—M. Pöchmüller offers the following statistics for the civil population: deaths due to infectious diseases, 3.27 per cent. as against 9 per cent. in 1911 and 6.29 per cent. in 1901. Typhoid fever represents over 25 per cent. of infectious diseases. The epidemics seem to be spread especially by contact.

Unilateral Pyonephrosis Following a Bullet Wound of the Bladder.—R. Lichtenstern considers the principal indications in bladder wounds (1) to assure the flow of urine, and (2) free drainage of the wound. The end to be attained is the prevention of urinary infiltration. Cystitis is an almost constant complication of these wounds and among the means at our disposal for treating this process is irrigation with a solution of Hg. oxycyanide, a salt which may cause irreparable renal lesions. Ascending infection of the ureters and renal pelvis is, in normal conditions, prevented by the tonus of the ureteral sphincters and to uphold this supposition, the writer relates two cases of bullet wounds involving the ureters, the outcome being a suppurating process in the kidney on the same side as the lesion. The ureter itself was very hyperemic. The diagnosis was made with the cystoscope which revealed an abnormal gaping of the ureteral orifice with a free flow of pus. Both cases were cured by nephrectomy.

Wiener medizinische Wochenschrift.

April 27, 1918.

Infectious Diseases at Belgrade in 1916.—M. Pöchmüller offers the following statistics particularly of tuberculosis and venereal diseases. Tuberculosis is responsible for 33 per cent. of the deaths, while acute infectious diseases resulted in only 62 deaths out of a total of 1300 cases. When the writer turns to the question of venereal infections the kind censor blots out all he has to say on the question, which is still another of the many endeavors to conceal the fearful spread of syphilis in the Germano-Austrian armies, well known to the profession of neutral European countries.

A Project of Medical Instruction According to a New Plan.—R. Stigler criticises the clinical teaching, practical exercises and examinations in European faculties, and makes what reads like a strong bid for American students to come for study to Germany and Austria after the cessation of hostilities.

Notes on the Etiology of Epilepsy, Particularly the "Epilepsy of War."—E. Redlich studies different conditions which may cause epileptic manifestations to arise. (1)Latent epilepsy aggravated by the war. Thus during the siege of Przenysl the admissions to hospitals for epilepsy increased 63.8 per cent. In these cases one could demonstrate the causative action of the war (privation, bombardment, etc.). (2) Epilepsy following upon epidemic meningitides. The writer includes under this head epilepsies which follow antityphoid or smallpox vaccinations.

A Case of Agenesia on the Middle Line of the Throat.—A. Nagy reports the case of a male patient presenting a vertical fissure filled in by the deeper seated structures. The malformation only involved the integuments and the larynx and trachea were normally developed and free from the defect.

The Oil Pimples of Shell Turners.—Those occupied in turning explosive shells on lathes suffer from a peculiar occupation disease, an eruption of pimples due to accumulation of iron in the integument. This accumulation is made possible by the use of impure oil.—*Le Progrès Médicale.*

Book Reviews.

A Pocket Formulary. By E. Quin Thornton, M.D., Assistant Professor of Materia Medica in the Jefferson Medical College, Philadelphia. Eleventh Edition. Revised. Price, $2.00. Philadelphia and New York: Lea & Febiger.

Concerning an eleventh edition there is little to be said. The present edition of this Formulary has been thoroughly revised by its author, and contributions relating to new and comparatively new remedies have been rewritten. It may be mentioned that the U. S. P. term "millimeter" has been adopted in this book to take the place of cubic centimeter. It is an extremely useful formulary.

Materia Medica, Pharmacology, Therapeutics and Prescription Writing. For Students and Practitioners. By Walter A. Bastedo, Ph.G., M.D., Assistant Professor of Clinical Medicine, Columbia University. Second Edition. Price, $4.00 net. Philadelphia and London: W. B. Saunders Company, 1918.

The bulk of Bastedo's book is devoted to pharmacology and therapeutics. In regard to the materia medica the author has wisely left out many things concerning drugs that are of more interest to the pharmacist than to the physician. In pursuance of this utilitarian plan, stress has been laid upon remedies of proven value and lengthy discussions on the theories of pharmacologic action have been avoided. The book is divided into three parts. The first part, comprising 63 pages, is of an introductory character, being concerned with such general topics as pharmaceutic preparations, weights and measures, active principles, the pharmacopœia, dosage, methods of administration, scope of treatment, etc. Part II deals with individual remedies, which might have been arranged in more logical order. Part III covers concisely the salient points of prescription writing. The section on digitalis in Part II is particularly worthy of note as representing the most recent ideas on the pharmacologic and therapeutic action of this important drug. The book as a whole is well written, is thoroughly up to date, and contains an excellent index. It is a sound treatise, especially useful to medical students and busy practitioners. The paper and printing as well as the convenient size all contribute to make an attractive volume.

The Anatomy and Physiology of the Female Body. By Hubert E. J. Biss, M.A., M.D., Cantab., D.P.H. Second Edition. Plates by Georges M. Dupuy, M.D. Price, $2.00. New York: William Wood and Company. 1917.

This atlas consists of five colored plates, each containing seven or eight separate colored figures. These plates show clearly the skeleton, the vascular system, the muscles, nerves, and chief viscera. There is a brief but adequate account of the body and its structure, and a detailed description of the colored plates. For the layman or nurse, and for purposes of teaching, this little book seems to be about as useful a work as can be desired. The colored plates are very clear, and they avoid the common error of including too many (unnecessary) details.

Details of Military Medical Administration. By Joseph H. Ford, B.S., A.M., M.D., Colonel, Medical Corps, U. S. Army. With 30 Illustrations. Published with the Approval of the Surgeon-General, U. S. Army. Price, $5.00. Philadelphia: Blakiston's Son and Co., 1918.

This book by Colonel Ford comes in the nick of time and supplies exactly what is needed. The vast majority of the medical officers of our army have not been trained as army surgeons and consequently lack knowledge as to the proper performance of the many duties which fall to their lot. The administrative duties of the military medical officer are by no means light. These are set forth clearly in a lengthy chapter written almost wholly by Major Roy C. Heffleblower, and the information therein contained should prove of great value to the medical officer newly entering the service. As noted in the preface, the work is a compendium of information gathered from many sources both at home and abroad, but the greater part of the text pertains to the American army. Colonel Gorgas in a short introduction to the book exactly expresses its value when he says that its publication is specially apt and appropriate. With his hope that every medical officer in the service will furnish himself with a copy, all will join. The work is well arranged and excellently illustrated.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia, assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. March 1, 1918. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger.

The March number of *Progressive Medicine* contains chapters on Surgery of the head, neck, and breast by C. H. Frazier; Surgery of the thorax, excluding diseases of the breast, by G. P. Müller; Infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by J. Rühral; Diseases of children, by F. M. Crandall, and Rhinology, laryngology, and otology by G. M. Coates. The present instalment is rather smaller than usual, but whether this is due to lack of material or to scarcity of paper we are unable to say. The contents are as interesting and valuable as usual, and the two first articles are particularly welcome, containing, as they do, sections dealing with war surgery.

Localisation et Extraction des Projectiles. Par L'Ombrédanne et R. Ledoux-Lebard. Deuxième édition remaniée. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1918.

The first edition of this volume was reviewed in these columns. There is no separate preface to the second edition and a comparison shows that it is an abridgment of the first, with a decrease of forty-four pages and twenty-seven cuts. As the number and titles of the chapters are the same the authors have evidently given the book a uniform downward revision. As no new matter has been added the present volume can hardly be regarded as a true successor to the first.

Tropical Diseases. A Manual of the Diseases of Warm Climates. By Sir Patrick Manson, G.C.M.G., M.D., LL.D. (Aberd.) Fellow of the Royal College of Physicians, London; Fellow of the Royal Society; Hon. D.Sc. Oxon.; Foreign Associate of the Académie de Médicine, France; Honorary Member of the Société de Médicine de Gand; Hon. Associate of the Royal Academy of Medicine, Turin; Consulting Physician to the Seamen's Hospital Society; Lecturer in the London School of Tropical Medicine; late Medical Adviser to the Colonial Office and to the Crown Agent for the Colonies, etc., etc. With 12 Color and 4 Black-and-White Plates and 254 Figures in the Text. Sixth Edition, Revised throughout and Enlarged. Price $6. New York: William Wood and Company, 1918.

A new edition of this standard work is always welcome. In addition to the new material necessitated by the recent advances in tropical medicine, the book has been thoroughly revised. Dengue is shown to be conveyed by the *Stegomyia calopus;* the chapters on mosquitos and the articles on tse-tse flies and ticks have been brought up to date; and some of the chapters have been rearranged or reclassified. The book remains the best practical and clinical manual on the subject of Tropical Medicine. The chapters on those topics with which Sir Patrick Manson's name is chiefly associated are the longest and most important in the volume. An entirely new section is included, containing a chapter on the vomiting sickness of Jamaica. This is, we believe, the first time that a description of this disease is to be found in any volume on the practice of medicine. There are a few misprints in this chapter; the disease is known in the island as *ackee* poisoning, not *ackers* poisoning; and the ackee is the fruit of the *Blighia sapida*, not *Blighi sapida*. The volume concludes with an appendix on some of the commoner parasitic protozoa of vertebrates and invertebrates.

Society Reports.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Annual Meeting, Held March 29 and 30, 1918.

JOHN A. KOLMER, M.D., OF PHILADELPHIA, PRESIDENT.

(*Concluded from Vol. 93, page 880.*)

A Method of Preparing Bacterial Antigens.—Lieut. J. C. SMALL, U. S. Army, presented this communication. This work was based on the fact that fat-like substances occurring in the bacterial cell greatly interfered in the aqueous solutions of bacteria. No entirely satisfactory method for extraction of bacteria had been accomplished. All methods were directed toward disintegration of the bacterial cell, with the idea of extracting the fragments, but this would be better accomplished if the fat and liquid constituents of the cell could be removed. In the present method a chloroform-ether mixture was used to extract the fat-like substances from dried bacteria. The residue was suspended in normal salt solution. The chloroform-ether extraction was found to break up the integrity of the bacterial cell, so as to facilitate its more ready extraction by aqueous solution.

Mr. CHARLES WEISS of Philadelphia said that the idea of removing the lipoid constituents was not an entirely new one. Some workers did not find it necessary to extract the lipoid; in some laboratories the custom is prevalent. Had the doctor checked up his results and found that they were different with removal of the lipoid to what they were without this procedure? In regard to heating of antigen, it was found in working with streptococcus antigen that heating destroyed the anticomplementary qualities.

Dr. J. A. KOLMER said that with regard to heating immune sera at 62° C. he thought there was deterioration of specific antibodies present in the serum. This was, however, difficult to measure, as it was hard to differentiate specific from non-specific factors. Observations had shown inhibition of bacterial antigen. It might be anticomplementary. It would possess the greatest degree of antigenic sensitization after heating at 60° C. for 1 hour. Higher temperatures were not used.

Miss M. A. WILSON of New York said that their experience had been that there was no deterioration. They did not add preservative to the antigen. It would depend to some degree upon the sera against which it was titrated. That serum might not be comparable at a later date, but the complement had the same fixation value at the time of testing. One could not say that heating inhibited.

Dr. H. VON WEDEL of New York said that he had used tubercle bacilli antigen and had heated it five or six times at intervals, and the value remained, as far as he could tell, exactly the same.

Dr. G. H. A. CLOWES of Buffalo said if the alkaloids were entirely removed the temperature could be raised considerably without causing any effect.

Lieut. SMALL said he had noticed the non-specific factors in a large series of animals which they were running for typhoid vaccines. Immunization was being carried on and complement fixations and a very large percentage of animals showed non-specificity. Sera, with the exception of para-A, did not show anticomplementary effect. In regard to checking up results, by using whole antigen, there was one dilution of typhoid antigen with lipoid removed, which when mixed with lipoid, would not give fixation.

Study of the Complement Fixation Reaction to Tuberculosis.—Miss M. A. WILSON of the New York City Health Department Research Laboratory presented this paper. Two points had been found to increase the efficiency of the test. First, standardization of the guinea-pig serum to determine the value of the complement; second, testing the patient's blood several days after bleeding. In making the test all reagents were used in 1/10 the classic Wassermann volumes. Fixation period, 1 hour at 37° C. The patient's serum was inactivated for 30 minutes at 56° C. Two antigens were used. One made from 12 stock cultures of human tubercle bacilli, the other from strain No. 305, used for production of tuberculin. When prepared the antigen was standardized to such dilution that 1 c.c. would contain 2 standard fixation units. The antigen was found not to be anticomplementary and gave uniform reactions. The complement was guinea-pig's serum, pooled from 6 to 10 pigs. This was done because many guinea-pigs do not produce serum which is fixable by tuberculosis antigen. It was found that if in the pool of 6 to 10 complements there were several strongly fixable, the presence of negative complements did not greatly affect the test; a preponderance of negative complements, however, would affect a true reaction to the patient's serum. The variability in fixability of guinea-pig serum was illustrated by tables.

Dr. H. VON WEDEL of New York supplied a paper representing the continuation of Miss Wilson's work. Briefly stated, his conclusions were: first, the tubercle bacillus antigen used was not anticomplementary for the majority of active tuberculosis cases; second, pooled complement from 6 or more guinea-pigs should be used in making the tests; third, double the original Wassermann amount of patient's serum should be used; fourth, sera should be kept under sterile conditions in the ice chest for 6 days before making the report. This six-day interval was necessary to the proper reading of the test. Fifth, if these points in technique were observed, it was found that 100 per cent. of non-tuberculous cases gave negative reactions; nearly 100 per cent. of primary active cases gave positive results (excepting dying cases); and about 25 per cent. of inactive cases gave weak positive results. Further study was needed on inactive and incipient cases, with controlled sera from non-tuberculous cases, in order to complete this work.

Dr. G. H. A. CLOWES of Buffalo said that in working on cancer cases and also syphilitic cases, reported 8 years ago, he had attributed the development of increase of complement deviation to the change in colloidal particles, due to being held in the ice box for a given period. He wished to ask what was the temperature of the ice box. Was the serum frozen?

Dr. VON WEDEL said that the ice box probably had a fluctuating temperature; it was more to keep the complement sterile, not to keep it cold.

Dr. PAUL LEWIS of Philadelphia said he had been much interested and instructed by these papers. The results should be valuable from a diagnostic point of view. He could add some data from his own experience from work done some years ago. At first he used bacterial suspensions of autolysate which, he found, lost rapidly in anticomplementary effect. Testing with the same serum day after day, it was found that one never got the same results on two days running. He thought the reaction was weak, and began using strong sera, at half an hour. He found one could get stronger fixations up to 6 or 8 hours. It was found that the complement could be put in the ice box and warmed up next morning, but it was necessary to carry controls always. The fixation power was titrated against the amount of complement which could be fixed, and such sera would give 4+ after 2 hours' fixation. It would fix 15/100 to 0.2 c.c. of guinea-pig complement. It was found that serum could be preserved in glycerin. It was probable that it increased in activity for a certain time. Guinea-pig complement was found to vary very much in its activity. If the animals were etherized, the serum must be left in the air till the ether evaporated. Complements could be incubated 4 hours, after that there was deterioration. Alcohol was used to avoid anticomplementary reaction.

Dr. WM. H. PARK said that he felt that this work should be used for primary cases, and later on they would be in a position to use it for a diagnostic basis.

Dr. J. A. KOLMER of Philadelphia asked if the peculiarities of the sera, that is the development of fixation properties, were found in the Wassermann and gonococcus complement fixation tests. He believed that the sera would be of more use in the gonococcus test than with T. B.

Miss M. OLMSTEAD of New York asked if the guinea-pigs which gave fixability with the tuberculosis antigen also gave fixability for the gonococcus antigen. How many specimens giving positive gonococcus results, were used for the tuberculosis tests.

Miss M. WILSON said that they killed ten pigs; ten were fixable for meningococcus; four for gonococcus; one for tuberculosis.

Dr. VON WEDEL said that there was absolutely no non-specific fixation. Every case that was negative clinically gave a negative reaction. The test was used day after day, and no change was detected in the serum. The antigen was heated from 50° to 60° C. for half an hour, and there were no antecomplementary results.

Dr. A. F. COCA said that if this work had any value it was bound to be practical, the value was not on the experimental side. It appeared to have the weakness of the Wassermann test, and of tumor reactions;—the question was not had the man a tumor, because the tumor can be felt, but "is it a malignant tumor?" This reaction, it was said, was found only in tuberculosis, so that if it was positive, the individual had had tuberculosis. The question "has the man ever had tuberculosis" was not so important as "in what stage is the tuberculosis?" That is, one wanted to know, whether the disease was progressing. The test did not show that. It could not be said as yet that it had great clinical value.

Dr. J. A. KOLMER said the antigen seemed to be free of antisyphilitic complement. In his experience with Miller's antigen, he found it gave some degree of fixation to the sera of syphilitics.

Dr. H. VON WEDEL said that no negative cases gave a four plus. No one would consider that a one plus Wassermann constituted syphilis. A strong positive was necessary. This was seen in the primary and secondary stages.

A Study of Controlled Post-mortem Wassermann Reactions.—Dr. STUART GRAVES of Louisville, Ky., read this paper. In sixty-eight cases studied he found that post-mortem reactions confirmed ante-mortem Wassermann reactions in 97 per cent. of cases. In cases showing anatomic lesions of syphilis, or with histories of syphilis, the sera post-mortem was positive in 91.2 per cent. of cases. Only 2.5 per cent. of sera were found unfit for use. Only 2.6 per cent. of three hundred and seventy-eight cases showing anatomic evidence of syphilis gave negative Wassermanns. Reactions were found to conform to historic evidence in 80.4 per cent. of three hundred and seventy-eight cases. No reason was found to suppose that other acute conditions caused a positive Wassermann reaction. The positive reaction was found twice as much in negroes as whites. The final conclusion was that one post-mortem Wassermann reaction was practically as reliable a test for syphilis as when done ante-mortem, and was of great value in pathological anatomy and in medico legal cases.

Dr. J. A. KOLMER said that he wished to endorse all that Dr. Graves had said. It coincided entirely with his own experience. He was familiar with the records just described. He thought it was particularly unfortunate that reports should be published, and should reach the general practitioner, which denied the practical value of the Wassermann reaction. No one who had dealt with pathological findings would deny that a pathologist cannot exclude syphilis on the basis of these findings alone. Spirochetes might not produce much reaction, yet they would produce antibodies, which would be indicated by the Wassermann reaction. In the last four or five years so much had been learned of the technique of the Wassermann reaction that one must agree that it was a test of great diagnostic value. While they must welcome attempts to point out sources of error, criticisms must be carefully controlled.

Miss M. OLMSTEAD of New York said that she was glad to hear Dr. Graves' statements. It had always been her impression that post-mortem Wassermann would bear out the ante-morten findings, but she had not as yet the figures to prove this point.

Election of Officers: *President*, Dr. William H. Park; *Secretary and Treasurer*, Dr. Arthur F. Coca; *Council*, Dr. George McCoy, to fill the term of Dr. Weil; Dr. Rufus Cole, to fill the vacancy left by resignation of Dr. W. J. Stone.

Observations on the Intraspinal Autosalvarsanized Serum Therapy of Cerebrospinal Syphilis.—Dr. BENJAMIN A. THOMAS read this paper. Cases of tabes were found, he stated, that did not respond to treatment. The spinal fluid sometimes gave a positive Wassermann reaction, when the blood was negative. In four years' experience the author said he had used autosalvarsanized serum. Intraspinous injection was given after intravenous injection, under careful sterile technique. An amount of spinal fluid was removed equal to the amount injected. The foot of the bed was raised after treatment. The treatment was continued till the spinal fluid was permanently negative. If improvement was found to follow intensive intravenous treatment, the intraspinal injections were not used. Degeneration of the cord was not affected by intraspinous treatment. Vascular cases were found to respond better to intravenous treatment alone.

Dr. H. ABRAHAMSON of New York asked was whole serum used, or was it diluted with salt solution.

Dr. J. A. KOLMER said that at the Philadelphia Polyclinic they had a large number of cases of syphilis under Dr. Schamberg's care. A number of intraspinous injections were given. They believed that something could be gained by salvarsanizing the serum in vitro after Ogilvie's method.

Dr. B. A. THOMAS said they had diluted neither serum nor spinal fluid. He thought that was an open question. He did not put the patient to the ordeal of intraspinous injection, if he could avoid it.

Experiments upon the Passive Transfer of Antibodies to the Cerebrospinal Fluid.—Drs. JOHN A. KOLMER and S. SEKIGUCHI of Philadelphia gave this paper, read by Dr. Kolmer. The summary of their work stated: The removal of blood from normal dogs, followed by intravenous injection of human syphilitic serum (30-50 c.c. per kilo body weight), caused small amounts of syphilis reagin in the cerebrospinal fluid. This reagin was found in the fluid as early as three hours after the transfusion of syphilitic serum. The amount of reagin found was small. After irritation of the meninges by sterile horse serum, more reagin was found in the cerebrospinal fluid. All traces of reagin disappeared from the cerebrospinal fluid of the dogs within forty-eight hours. Dog-typhoid immune serum, injected into a normal dog, intravenously, caused traces of agglutinin to appear in the cerebrospinal fluid within three hours; it disappeared within forty-eight hours. It was thus shown that the passage of antibody from the blood to the cerebrospinal fluid was possible, when the antibody existed in the blood in high concentration. In human syphilis the reagin might pass from the blood, but its presence in the spinal fluid generally indicated the presence and activity of *Treponema pallidum* in the nervous organs.

Dr. A. P. HITCHENS said that the question whether the antibodies would find their way from the blood to the spinal fluid was important, especially in cerebrospinal fever. In severe cases of meningitis in the army camps they gave intravenous doses as well as intraspinal of the antimeningitis serum. Results of the treatment were encouraging. Dr. Kolmer's work would show that this line of treatment was of value.

Dr. J. BRONFENBRENNER said it was a question as to whether bodies could pass from the blood into the spinal canal. He doubted whether this was possible when the pressure was higher in the spinal canal than in the blood. English workers had concluded that there was a toxin produced by the meningococcus and that this toxin was forced from the spinal canal into the blood stream. If this contained antitoxin it would get into the serum and the improvement would be due to that. Dr. Hitchens said about every eight hours during the severe part of the disease the spinal fluid was removed, and with the rapid filling up of the canal again there might be some effect.

Dr. J. F. KOLMER said that the paper simply dealt with the passage of antibody from the blood to the spinal fluid under normal conditions. In the experimental animal there was a large amount of antibody in the circulation. He could not agree with Dr. Bronfenbrenner's remarks on the spinal fluid. This is a secretion of the choroid plexus, at least during health. Even when the fluid is high, production continues and increases hydrocephalus. Evidence would prove that the fluid is produced continuously even after rise of pressure.

Vaccine Dosage.—Dr. JOSEPH HEAD of Philadelphia read this paper. He stated that in former times he

had been in the habit of giving large doses (as much as eleven hundred million) of mixed germs, and in 90 per cent. of cases he used to get good results. He had found, however, that some patients got undesirable symptoms with a dose as low as thirty thousand, and he had proved that the tolerance of some patients should be carefully ascertained. He thought it was better to keep the injection below the point of getting reactions. He now began with small doses, which, if borne well, were increased. Reactions were of various types, and sore throat and colds were often typical reactions. A dose just short of a reaction gave the best final result.

Dr. A. P. HITCHENS said it was necessary to have followed Dr. Head's work to appreciate the enormous amount of experience that he had brought to bear. Vaccine therapy was an instrument which had to be carefully studied in order to be used with confidence. Dr. Head had been the acknowledged leader in such work for many years. Dr. Hitchens had never used such small doses, but Dr. Head's experience made him think seriously of it.

Dr. J. A. KOLMER said if it was anyone else than Dr. Head he would raise a point of issue, but results could guide one here, rather than theory. Dr. Head's results were comparable with the use of tuberculin in tuberculosis. Large doses would produce rapid tissue destruction.

Dr. HEAD said that no one had been more surprised in finding out these facts than he had been himself. He had found that small doses had greater therapeutic effect. They apparently acted in a different way. Perhaps later he would have a theory to explain it.

Vaccine Treatment of Acne, with Special Reference to the Role of B. Coli.—Drs. A. STRICKLER and J. F. SCHAMBERG of Philadelphia presented this communication. Thousands of cases of this disease, it was stated, never came to the physician at all, it was only when suffering from severe forms with great disfigurement, that the patients sought advice. The lesions were chiefly in the sebacious oil glands which were very active at puberty. Puberty was, in fact, the primary predisposing cause. Anemia and constipation were found to be pretty constant accompaniments to acne. It often developed after typhoid fever, and intestinal intoxication evidently played a role in the etiology. In the treatment of acne by vaccines, it was found there was a complement fixation in 63 per cent. of cases from an antigen prepared from colon bacillus isolated from the intestinal tract of the patient. The fixation was higher when the antigen was from the patient. It was resolved to treat fifty cases with no other means than by vaccines prepared from an autogenous colon bacillus. These cases were controlled by cases treated by other methods,—vaccines from other germs, therapeutic and hygienic measures. The *B. coli* vaccines were found to possess better curative effects than any other mode of treatment.

Dr. J. F. SCHAMBERG said he would like to emphasize one or two points. Vaccines prepared from *B. acne* and from staphylococci had been used for many years, and in some cases had given brilliant results, in others they had failed to respond. The present experiments were tested out in a hospital clinic with a large number of patients. Sixty-three per cent. gave positive complement fixation to the strains of *B. coli* used for the vaccines. A large percentage of patients responded to a remarkable degree. It was likely that at puberty, when there was great developmental activity, that there was liability to infection from the intestinal tract. The activity of the intestinal organisms would then produce noxious effects. The complement fixation tests would incriminate especially the colon bacillus.

Dr. A. F. HITCHENS said it would be an important point to find out which strain of the *B. coli* was the important factor in producing the disease. Had any work been done on the sera in this respect?

Dr. A. STRICHLER said that, personally, now he welcomed an active case as he felt that a good deal could be done for the patient. Formerly he had rather dreaded to see such a patient come, as the results of treatment were so often disappointing.

Dr. F. J. SCHAMBERG said that no attempt had been made, as yet, to differentiate strains. The complement fixation test showed that there was great specificity to the *B. coli* from active cases.

Lipovaccines.—Lieut E. FENNEL, M. C., U. S. A., read this paper, the result of his work with Col. E. R. WHITMORE. The advantages of lipovaccines were stated:—Autolysis was reduced to a minimum, absorption was slower; the reaction was far less in sensitized persons. If oil were used as a vehicle, the entire amount could be given at one dose, and the reaction could be lessened. These latter points made this method a very desirable one for army procedures. Experiments were, therefore, begun on triple typhoid vaccines; triple dysentery; pneumococcus, and a meningococcus lipovaccine. It was found, after several series of tests, both on men and animals that these conclusions were justified: (1) the lipoid vehicle markedly reduces the toxicity of otherwise toxic strains; (2) vaccination against vacillary dysentery is entirely practicable; (3) a high-grade immunity is stimulated.

Dr. A. P. HITCHENS said that this plan for the preparation of bacterial vaccines was likely to be of immense value. If one could give the entire treatment in one day, the economic value was obvious. At Camp Beauregard he saw a detachment injected with meningitis lipovaccines; the reactions were very severe, as were also those from triple typhoid vaccine. The meningitis vaccine caused severe headache and insomnia. All the symptoms disappeared next day. He felt great confidence in the outcome of the work of Lieutenant Fennel.

Lieutenant FENNEL said there was a very severe reaction to the first vaccine they used. Since the improvement in technique the severity of the reaction was absent.

A Study of the Immunizing Properties of Bacterial Vaccines, Prepared After Various Methods.—Mr. M. W. PERRY, Dr. JOHN A. KOLMER and Miss S. LEVY of Philadelphia presented this communication. Both specific and nonspecific effects of bacterial vaccines were considered, the former being the production of specific antibodies, as agglutinins and lysins for the bacterial protein; the latter being the temperature, the leucocytic response, the mobilization of ferments, and other phenomena. The experiments were conducted to test the antibody response to each, as well as the nonspecific phenomena. Rabbits were used, and the dosage was calculated per body weight of the animal. The vaccines used were: (1) Autolysates; (2) heat killed vaccine; (3) Tricresol killed vaccine; (4) mercurophen killed vaccine; (5) living vaccine, freshly prepared; (6) alcohol killed sensitized vaccine. The conclusions were: I. All vaccines of *B. typhosus*, prepared in various ways, usually produced slight leucocytosis and slight rise of temperature, when injected subcutaneously into rabbits, in dosage comparable to those given to persons. These nonspecific reactions were most marked to alcohol killed sensitized vaccines. II. Agglutinin and complement fixing antibody production was most marked in response to injection of living and autolysed vaccines; next came in order: mercurophen killed, tricresol killed, heat killed, alcohol killed sensitized vaccines. III. While agglutination and complement fixation reactions showed some tendency towards specificity for their particular *B. typhosus* antigen, this specificity was not marked. IV. An antigen of *B. typhosus*, prepared by cultivating the organism in plain neutral broth for forty-eight hours, plus 0.1 per cent. commercial formalin, sterilized in a cold, dark place for four days, was the best for the macroscopic agglutination test. The various vaccines of *B. typhosus* were arranged as follows in order of antigenic sensitiveness: living and autolysed; mercurophen killed, tricresol killed; alcohol killed; and heat killed. The last was least antigenic.

Lieut. E. FENNEL asked Mr. Perry if he titrated the agglutinable culture by the standard set by Oxford. If so, the results would be of considerable value for the army work.

Dr. J. A. KOLMER said the culture was secured from a German University, sixteen years ago, and was standardized for agglutination work. It was highly susceptible to agglutination. It was not standardized by the Oxford method.

Dr. A. P. HITCHENS said that the number of prob-

lems in connection with vaccines had discouraged many in their use. There was no doubt, however, of their prophylactic efficiency, as in the case of typhoid. As to methods of killing bacteria, heat, and also tricresol were efficient. Possibly there would be some other method found to make a rapid production of antibodies. One could produce enormous amount of agglutinins, but when it came to treatment there were many variable factors. The problems, however, must be attacked, or they would never get anywhere.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Twelfth Annual Meeting Held at Albany, May 21, 22, and 23, 1918.

(*Continued from Vol. 93, page 968.*)

SECTION ON MEDICINE.

Etiology of Nephritis.—Dr. CHARLES JACK HUNT of Clifton Springs, presented a study of 342 cases of nephritis, 60 of which were studied by the methods outlined by the author. Of these 60, 47 were submitted to corrective and dietetic measures as advised and were subsequently restudied. The longest period of observation was two years and the shortest 26 days, following corrective measures. Correspondence with the home physicians of the group secured replies from the majority of them or from the patients, and in a few instances from both. Of the 23 cases uncorrected, 3 had died from nephritis, 16 reported advance of the disease or no improvement; 4 were not noted. Of 47 cases submitting to corrective measures, 9 had not been noted, 6 reported little or no change, and 30 much improved or apparently as good as ever. The latter quotation "much improved" appeared frequently enough to be used as a general statement. Culture study showed the streptococcus mucosus as the principal pathology. Other bacterial forms, in the order of frequency, were a diphtheroid organism, bacillus mitis, streptococcus candidus, streptococcus viridans, and pneumococcus, of 47 cases restudied. Thirty-six were reported prior to the presentation of the paper. Of these 30 were improved and had resumed normal modes of living. Of 23 cases not corrected, 19 were reported, 3 having died, and 16 showing advance of the disease.

Dr. CHARLES G. STOCKTON of Buffalo stated that he did not know just how carefully or how radically the essayist classified his cases of nephritis, but it did not seem to make very much difference because as these cases were seen they were either primarily from infection alone or from a mixture of infection and metabolic defect, and in the management of all cases it was up to the practitioner to get rid of infection and correct the metabolic defect.

The Diagnosis of Nephritis.—Dr. ALBERT A. EPSTEIN of New York City stated that on the basis of our present knowledge a diagnosis of nephritis was confronted with two distinct problems. First, the determination of the pathological processes involved; and secondly, the evaluation of the kidney function. An accurate diagnosis of nephritis therefore entailed a circumspect and complete analysis of all the morbid conditions present; the probable etiological factors involved, the disturbance in functions and other disorders which arose therefrom. To regard nephritis as an independent condition was a fallacy. The existence of acute nephritis, excepting, of course, the chemical nephritides and the types occurring in pregnancy, pointed usually to an antecedent infection. But renal disorders with urinary signs frequently occurred in febrile diseases of all kinds, which did not represent true nephritis, and thus the problem of differentiation often arose. In the matter of chronic nephritis, the problem of etiology as a source of information was much more difficult. No doubt in a certain number of cases a history of acute nephritis or recurring infections might be elicited, and a diagnosis made, but the connection between the two was not always clear. Chronic poisoning, tuberculosis, and syphilis might be contributory factors and required consideration in the diagnosis. There was one difficulty that presented itself from the clinical side in investigating the question of the connection between acute, subacute, and chronic nephritis, and that was, that acute and subacute nephritis might appear without the development of symptoms other than the urinary signs during any infection. Furthermore, in the chronic nephropathies it was the possibility and the frequent occurrence of compensatory processes that created difficulty in arriving at a diagnosis. This was particularly true when the question was viewed from the functional standpoint. In the application of functional tests in the diagnosis of nephritis, two points should be borne in mind, namely, that a number of the different functional tests should be made and that they should be repeated in each and every case. As a prerequisite to the proper interpretation of the results obtained by functional tests, extrarenal factors which were capable of modifying or influencing them should be definitely excluded.

Pathology of Nephritis.—Dr. HERBERT U. WILLIAMS of Buffalo stated that the pathology of nephritis was in a rather confused state. Efforts were now being made to connect the diseased conditions that were found and their structures with the causes of these diseased conditions on the one hand, and, on the other hand, to connect these diseased conditions with changes in substance. The chronic form of glomerular nephritis was by many held to be identical with chronic interstitial nephritis. There was great difficulty in separating these from the arteriosclerotic kidney, which resembled it closely in many cases. As a matter of fact, it was exceedingly difficult to draw a hard and fast line between the different types of nephritis not only clinically but anatomically. To be perfectly safe one should call every case of nephritis diffuse pretty nearly always. In recent years there was a tendency to attribute the granular contracted kidney to earlier attacks of glomerular nephritis. The formation of new fibrous tissue in a kidney leading to chronic interstitial nephritis seemed more and more to be attributed to the formation of fibrous tissue in response to a loss of substance rather than as a result of irritation. We were not able at the present time to connect the pathological anatomy very closely with changes in function. The classification of nephritis into glomerular, tubular, the late glomerular, the chronic interstitial and the arteriosclerotic was quite generally adopted, and the most interesting point was that of determining the relation of focal infection to glomerular nephritis by finding it was actually caused by bacterial emboli and not entirely through the agency of toxins. Finally, a number of authorities were of the opinion that granular contracted kidney was closely connected with the arteriosclerotic kidney, and hard to tell from the latter. He quoted Mallory as saying that a patient who recovered from his toxemia and from his acute attack might suffer almost equally from the reparative changes which occurred in the kidney.

Treatment of Chronic Nephritis.—Dr. JOHN R. WILLIAMS of Rochester stated that the most common type of kidney disease seen was that of the middle aged adult who complained of some or all of the following symptoms: tiring easily, occipital headache, shortness of breath, high blood pressure, and little or no physical evidence of kidney disturbance except frequent and excessive urination at night. The blood was commonly low in urea, creatinin and phosphates, the blood sugar might be high. Edema was usually not present. Death was rarely caused by uremia, rather by cerebral hemorrhage or failing heart. This was the well known cardiorenal type. The next most frequently seen type was the middle aged or even younger adult who might have pronounced eye symptoms, edema, low or high blood pressure, very little kidney reserve, urine loaded with albumin and casts, blood containing two or three times the normal amount of urine, a high blood sugar, increased blood creatinin and phosphate retention. Death was commonly preceded by convulsions and the phenomena of uremia. The last and much less frequently seen type was that of the young or middle aged adult who complained chiefly of edema, weakness, pallor, and not albuminuria, blood urea, and sugar would be found low, perhaps lower than normal. The cholesterin content of the blood might be greatly increased; edema might or might not be influenced by the salt content of the diet. The functional capacity of the kidney was fairly normal to the usual clinical tests. The patient suffered very little headache or from other symptoms commonly seen in kidney failure. The first

and one of the most important steps in the treatment of any type of kidney disease was to rid the body of all focal infections. The matter of investigating suspicious tonsils, crowned teeth and diseased prostates could not be overemphasized. In the treatment of the cardiorenal type if one had made sure that the patient was not harboring infection, the most important measure was rest, both mental and physical. If the patient had a good functional kidney capacity he should be put on a low general simple diet. All chemical irritants in the way of spices, mineral acids, alcohol, and foods containing quantities of animal extractions, bacteria and bacterial products should be excluded from the diet. The patient should be allowed to have some meat and eggs. The second clinical type demanded quite a different therapeutic regime than did the cardiorenal type. In severe cases the best internal measure was to put the patient at rest and give him a limited milk and fluid diet as first suggested by Karell. The author prescribed for the first few days one quart of milk, one pint of water, and either another pint of lime water or some salt of calcium, either the carbonate or lactate in half gram doses several times daily. The tincture of iron or ferrous carbonate in liberal doses was also given. In the third and last common type of chronic kidney disease the diet should be more liberal and should contain a large amount of protein. As many as 8 to 10 ounces of meat may be very helpful. Fluids should be restricted. If there was evidence of salt retention its use should be curtailed, otherwise it might be sparingly permitted.

The Clinical Significance of Congenital Anomalies of the Kidney and Ureter.—Drs. JOSEPH R. LOSEE and HENRY G. BUGBEE of New York City described the development of the organs of the upper urinary tract in the human and traced their relationship to various anomalies. Among the 22 cases of anomalies reported by the authors were one case of single kidney, one case of calculus obstruction of the ureter, three cases of horseshoe kidney, one case of fused kidney, one case of duplication of the kidney pelvis, and one case of incomplete duplication of the right kidney pelvis, and colon bacillus infection. Cases of anomalies of position of the kidney were reported. In one case the right kidney was low and had not rotated. In another case the kidney had migrated to the opposite side. Cases of anomalies of the ureters were reported. The surgical treatment consisted in relieving pressure, placing the kidneys in their normal position, removing any obstruction to renal drainage, removing the diseased kidney when destroyed beyond repair if the opposite kidney was able to carry on its function. If it was not possible to make a positive diagnosis of the extent of the lesion before operation, operation should include exploration of both kidneys.

Congenital Hydronephrosis.—Dr. JOHN T. GERAGHTY of Baltimore said there was a group of cases which had been puzzling practitioners for years. He referred principally to so-called primary hydronephrosis. The term primary had been used in these cases because there had been no etiologic factor that could be easily determined as the cause of this kind of hydronephrosis. Many of the cases had been considered congenital and physicians had been of the opinion until recently that most of the cases in which we could actually determine any cause for the extreme process were congenital. Recent studies, however, had shown that we were wrong. There were two types of aberrant vessels which were most apt to cause hydronephrosis. In one instance the vessels arose from the aorta behind the ureter and entered into the lower surface of the kidney at its lower pole. In the second case the vessel arose from the vena cava, crossed the anterior surface of the ureter and entered the posterior surface of the kidney. These two conditions gave rise to a condition which produced obstruction. In a series of 15 cases, in only two was he able to find aberrant vessels as the cause of hydronephrosis. The vessel crossed at the uretero-pelvic junction, but further studies showed that this possibly was merely a coincidence. Marked kinking of the ureter or pressure of a vessel crossing over the ureter was not sufficient to produce hydronephrosis. However, in some cases of unusual mobility where the kidney dropped down over the aberrant vessel, that vessel might play an important role. Even though aberrant vessels were found it was well to bear in mind that might not be the primary cause. There might be other factors that played a casual role. Renal mobility was put forward as a common cause and most urologists gave it first place. In the author's experience it had been the most common cause of hydronephrosis. In the series of 15 cases, in 10 nephrectomy was performed. He had the tissues to study and sufficient of the ureter removed to study the cause of the hydronephrosis. In three cases plastic procedures were carried out, and in two cases aberrant vessels were divided. In a study of these 10 cases, with one exception, there was found at the uretero-pelvic juncture, or in the upper part of the ureter, an inflammatory infiltrate. Most of these cases were considered congenital beforehand, but sections through the ureter in studying the pelvis showed varying amounts of infiltration. Hunner, he said, had called attention to pyogenic infiltrations in the lower ureter and he had found them common in women in the region of the broad ligament. These infiltrations of the ureter caused dilatation of the ureter and pelvis which were frequently seen and which Dr. Braasch had considered an inflammatory dilatation. It represented a narrowing rather than a definite stricture, with obstruction rather than dilatation of the process in the kidney and ureter itself. Inflammation did not give rise to dilatation but rather a contraction, The diagnosis of hydronephrosis was not difficult. With the methods now at our command it was possible to make a diagnosis of hydronephrosis by pyelography and to demonstrate the exact point where the hydronephrosis began. In most cases the kidney was destroyed when the patient was first seen. At any rate, it was either badly infected or the kidney was destroyed. Nephrectomy was the proper treatment.

The Prognosis of Surgical Renal Tuberculosis.—Dr. WILLIAM F. BRAASCH of Rochester, Minnesota, stated that in considering nephrectomy for early unilateral tuberculosis the factors to be considered were age, sex, coincident tuberculosis in other organs or tissues, the duration of the symptoms, the severity of the infection of the urinary tract, and whether there was or was not bilateral involvement. The statistics of the Mayo Clinic were given. Age was a factor of considerable importance in the diagnosis. The incidence of renal tuberculosis occurred from 25 to 40 years of age. Beyond the age of 60 or 70 years renal tuberculosis was of rare occurrence. They had operated on three cases up to ten years of age. In the meantime they had seen 40 cases in children up to ten years, not operated, because renal tuberculosis in children was very frequently a part of a general tuberculosis. The children on whom they had operated were seen early and tuberculosis was not found present elsewhere. It was not customary to operate on children at once because the majority of cases sooner or later showed other evidences of tuberculosis and their resisting power would be low. As to the time to operate, it was between 25 to 40 years of age, as the mortality increased steadily with the advance in years. The greatest mortality occurred in patients from 50 to 70 years of age. The lowest mortality from operative intervention occurred in patients from 15 to 20. The influence of complications on the mortality was important. The majority of cases had evidences of tuberculosis in other organs of the body. In only 5 per cent. was the renal tuberculosis complicated by acute pulmonary tuberculosis. Ninety per cent. of the cases of renal tuberculosis had evidences of an old pulmonary tuberculosis. Of the cases of pulmonary tuberculosis complicated by renal tuberculosis, 21 in number, 40 per cent. died, which was twice as high as the mortality from renal tuberculosis uncomplicated by pulmonary tuberculosis. However, if they had not operated on patients with both pulmonary and renal tuberculosis they all would have died. It was inconceivable to think of a spontaneous cure of renal and pulmonary tuberculosis. The removal of the epididymis when enlarged or markedly inflamed, with secondary infection, was unquestionably advisable following nephrectomy. It was their experience at the Mayo Clinic that the caseating kidney offered a much better prognosis and a much less mortality than miliary tuberculosis. In miliary tuberculosis scattered over the

surface of the kidney the mortality was higher than where caseation was present. It was almost twice as high.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting Held March 27.

Hemianopsia.—Dr. Francis X. Dercum presented this patient. The case occurred in a man, 67 years old, who came under treatment for a diverticulum of the esophagus. While under observation he became aware rather suddenly of loss of vision in the right visual field of each eye, without other accompanying symptoms. The blood-pressure was high and the superficial vessels were tortuous and resistant. The Wassermann reaction was negative and there were no visible changes in the fundus oculi. Under treatment with potassium iodide gradual improvement was taking place in vision. The conclusion was reached that there had been a temporary occlusion of the blood-supply to the cuneus on the left side of the brain.

Tremor Following Wounds Inflicted in the Russo-Japanese War.—Dr. Dercum also presented this patient, a married tailor, 36 years old, who had received multiple injuries while serving as a soldier in the Russian army in 1905. Since that time he has exhibited tremor in different parts of his body, in addition to a subjective sense of tremor at times without objective manifestation.

Tumor of the Brain.—Dr. Alfred Gordon presented this case. The patient was a man, 29 years old, who illustrated, among other things, the extraordinary tolerance of the brain to surgical operation. Some 3 or 4 years before he had suffered from severe headache, with vomiting and attacks of fainting. On one occasion he fell on the street and was taken to a hospital, where a trephine opening was made in the right parietal region. No lesion was discovered, but great relief from the previous symptoms followed. However, left hemiplegia developed, with convulsions confined to the left upper extremity, sometimes with, other times without, loss of consciousness. In the course of time a considerable hernia cerebri developed and headache returned. At this time a Wassermann reaction yielded a negative response, and papilledema was found in each eye. In the hope of affording relief a segment of skull was removed from the left parietal region, again with relief from the headache. However, transitory weakness on the right side of the body, with temporary aphasia, appeared, while bilateral optic atrophy developed together with paralysis of the left external rectus and the right internal rectus and there was a tendency to fall toward the right side. With recurrence of the headache, and having in mind the possibility of a cerebellar lesion, a subtentorial occipital operation was performed and again with temporary relief from the distressing symptoms. Finally the headache again became intolerable and hernia cerebri becoming pronounced on the right side the opening on that side of the skull was enlarged. The patient still exhibits weakness on the left side of the body with occasional convulsive seizures confined to the left upper extremity, preservation of tactile sensibility in the left hand, but with astereognosis and loss of sense of position in this member, and optic atrophy; but otherwise he is in good health. The belief was expressed that the underlying condition is a slowly developing new growth in the right frontoparietal region.

Intrauterine Poliomyelitis (?).—Dr. Charles S. Potts presented this case, which occurred in a man, 54 years old, who from birth exhibited muscular and bony deficiencies and deformities in different parts of the body with electrical changes, and whose origin was attributed to an attack of poliomyelitis during intrauterine existence or perhaps to developmental aberrations.

Chloroform Deaths.—Auvray in 3500 surgical operations performed during the present war, reports 3 anesthetic deaths. After the last of these he changed to ether, the inconveniences of which are negligible in comparison with the stigma of causing death.—*La Presse Médicale.*

Miscellany.

The Society for Legal Medicine and Criminology of Bahia.—The study of medical jurisprudence is evidently a favorite one in Bahia. A course of legal medicine is given at the University there, while the State conducts a School for Police and the Nina Rodrigues Medicolegal Institute publishes official archives at the State's expense. These several bodies are closely affiliated under central control. Up to 1915 there had been defended at the University of Bahia 121 theses on medicolegal subjects, the oldest going back to 1839. At first but few were published—twenty up to 1859, an annual average of one. There was then for some reason a complete interruption until 1884. During the six years, 1884-1889, inclusive, twenty theses appeared. They then became scattered until 1897, since which year a good average has been maintained. Over half of the theses have appeared since 1900.

In reviewing the titles we are impressed by the small rôle played by insanity, while criminality is well represented. Personal identity, finger prints, tattoo marks, and anthropometry, stigmata of degeneration, the criminal instinct, behavior of prisoners, insanity, and crime are considered equally with criminal abortion, rape, criminal poisoning and other more familiar themes. In other words, the professional criminal as well as the incidental or amateur offender receives full consideration, something which the older forensic medicine largely ignored.

Prophylaxis of Venereal Disease.—Sabouraud, in an article abstracted in the *Journal de médecine et de chirurgie pratiques* for March 10, laments that the efficacious methods of venereal prophylaxis in the American Army and Navy which were originally devised by the French have not until recently been utilized by the latter. These diseases continue to increase in soldiers and civilians alike. The American soldier is fully enlightened and threatened with punishment for certain infractions and actually punished for disobedience. After coitus he must at once present himself at a prophylactic station. This resource, only recently introduced in France, has been operative in the United States Army since 1911-12. At the outset the soldier was punished only when he failed to report for prophylaxis at all and later he was punished when he did not appear with the required punctuality. Otherwise stated, he is now punished for allowing himself to become infected. Contamination is evidence of breach of discipline. In addition there are regular days of inspection in the barracks and a soldier found contaminated is subjected to a sort of court martial. He may have his pay suspended for two or three months.

The general result of prophylaxis is the contamination of only one-half of one per cent. of those exposed. Since the establishment of stations in Bordeaux there has been but one contamination for 1,000 exposures. The alternative is, perhaps, as many as 15 contaminations for every 100 men exposed. Good results are seen wherever the prophylaxis is used and the latter was devised many years ago in the Pasteur Institute by Metchnikoff and Roux.

THE VALUE OF DICHLORAMINE-T CHLORCOSANE SOLUTION (DAKIN-DUNHAM) IN THE TREATMENT OF INFECTIONS OF THE UPPER AIR PASSAGES.

By D BRYSON DELAVAN, M.D.,

NEW YORK.

The present war has brought a distinct advance in our knowledge of surgical infections and of the means for their prevention and relief. Of recent measures none has deserved greater attention than the so-called Dakin method for the disinfection of wounds. The advantages of this have been widely tested and convincingly proved. Of its value there can be no doubt.

The basis of the solution by means of which the Dakin treatment is carried out is a greenish-white crystalline substance possessing a sweetish, rather pungent, chlorous odor, stable in the solid state, especially when kept in the dark. It is known as dichloramine-T (toluene-p-sulphon-dichloramine). It has an intense germicidal action corresponding with its high content of chlorine. It is difficult, however, to find satisfactory solvents for it which will yield stable solutions. The experiments carried on by Dr. Dakin, in company with Dr. Edward K. Dunham of New York,* have proved that the best medium thus far found by them is an oil obtained by the chlorinization of paraffin wax, to which has been given the name "chlorcosane." Other solvents which they have experimented with are a mixture of eucalyptol and paraffin and one made by the prolonged chlorination of eucalyptol. Chlorcosane has seemed decidedly preferable. Dakin and Dunham thus describe the way in which the antiseptic action of dichloramine-T in the solution is exerted: "It is well recognized that antiseptics incorporated with or dissolved in oily substances usually possess little if any antiseptic activity, because intimate contact with the infected matter is hindered by the oil. When, however, such oil solutions of dichloramine-T as will be described are brought in contact with aqueous media, the partition coefficient between the oil and the water is such that a certain amount of the dichloramine-T passes into the water and there exerts its germicidal action. The amount of dichloramine-T thus passing from the oil is enhanced by the presence in the aqueous medium of substances capable of taking up chlorine, so that the oil solution serves as a store for the antiseptics, which is drawn upon to maintain the germicidal activity of the aqueous medium with which it is in contact. Thus the amount of antiseptic leaving the oil solution is, to a certain extent, dependent upon the rate at which it is used up in the aqueous medium."

The dichloramine-T oil solution may be sprayed upon wound surfaces or poured into accessible parts of deep wounds. It yields a moderate amount of the antiseptic to watery media, such as secretions from wounds or mucous membranes. It is suitable for cases requiring prolonged antiseptic treatment and for first dressings of wounds which do not require irrigation. The application of the oil is extremely simple and in the treatment of wounds it ordinarily need not be renewed more than once in twenty-four hours.

The highly active germicidal qualities of dichloramine-T having been demonstrated in general, it becomes a matter of great interest to study its value in the upper air passages, regions especially liable to infection, prone to harbor germs of dangerous character, abounding in recesses difficult of access by the ordinary means of application, and often becoming foci of infection threatening extreme danger.

Of the various parts of this region the upper half of the nasal cavities, the tonsils, and the vault of the pharynx seem the most susceptible to infection and the hardest to reach. They may be invaded by a wide variety of harmful microorganisms, including the staphylococcus, the streptococcus, the pneumococcus, the meningococcus, the bacilli of diphtheria, and, in fact, almost any of the active infections, not excepting those of measles, scarlet fever, and grippe. The successful disinfection of these parts therefore becomes a matter of wide interest and serious importance.

Applied for this purpose in the upper air passages, the dichloramine-T may be used with advantage under three different conditions: (1) To prevent the development of newly acquired infection; (2) to overcome the acute results of infection; and (3) to abolish the bacilli persisting in carriers.

Thus, it has been found effective in the prevention of cerebrospinal meningitis and of measles through its early aplication in subjects who have been exposed to those diseases, and in other analogous situations it has proved a valuable safeguard.

Its value in acute infectious conditions of the tonsil has been tested by the writer and others during the past winter. There are many like conditions of the nasal cavity in which its use has already been found advantageous.

A third and very interesting situation promising

*A Handbook of Antiseptics by Henry Drysdale Dunham and Edward Kellogg Dunham, New York: The Macmillan Co., 1918.

important results is the disinfection of co-called "carriers." Recent investigations in the medical service of the U. S. Government and elsewhere have proved that carriers of infection are commonly met with, that their presence is associated with great danger to others, and that the means heretofore used to disinfect them have often proved unsatisfactory. In the Dakin-Dunham solution we have a germicide which has already proved itself superior to those in ordinary use in that its disinfectant action is more powerful, its activity more profound, and its local effect less irritating. The best results to be obtained from it, however, have not always been secured. In order to insure them, the anatomy of the tonsil and of the nasal cavities must be clearly understood and the inaccessibility of their parts recognized.

The value of the method must, of course, depend in an important degree upon the thoroughness with which the disinfectant is applied to the ultimate recesses in which the germs are lodged.* Brushing the surface of the tonsil or spraying the lower section of the nasal cavity with the solution cannot possibly be effective as long as the remote parts are not reached. The reason why the attempted disinfection of infected throats and nasal cavities has sometimes failed is because this all-important principle has not been recognized. The writer has been experimenting for some time past with various methods calculated to secure the intimate contact of the oil solution with foci of infection in the upper air passages too remote to be reached by the ordinary methods. He has adopted a procedure based upon the simplest mechanical principle, which has yielded the best practical results thus far obtained. Its neglect is a frequent cause of disappointment. *This principle consists in the most complete possible exposure of the parts, preliminary to the application of the oil.* As far as can be learned, this suggestion heretofore has not been advanced or carried out. In the case of the tonsil, it is the crypts which harbor the most persistent of the offending organisms. It is absolutely essential therefore that these crypts should be disinfected to their lowest depths. In the nose the complicated structure of the superior half of the nasal cavity necessitates that it receive especial attention.

For example, to secure the thorough treatment of the tonsil it should first be cleansed with some mild alkaline or salt solution by means of a spray carried into the crypts. Immediately following this, a spray of adrenalin or other similar astringent should be carefully applied for the purpose of contracting the tonsil and thus exposing its recesses. When this has taken effect, the crypts should again be sprayed with the cleansing solution to rid them of all obstructing secretion. Finally the dichloramine-T solution, driven in the form of a spray, must be applied to all crypts and pockets of the tonsil and caused to penetrate to their lowest depths. This is usually not difficult of accomplishment, as the force of the air current from the spray tube causes the crypt entrances to open widely and the crypts themselves to balloon out until they are distended to their capacity, in which position the oil can enter with complete thoroughness. This course of action is absolutely necessary, since attention alone to the surface of a thoroughly infected tonsil can not succeed.

What is true of the tonsil is even more positively the case with the upper nasal region. The parts lying above the inferior margin of the middle turbinated body are not often freely accessible to any spray. Under the influence of infection they become still less so, by reason of the turgescence and swelling of the soft parts. To be effective, the spray must be driven directly into the affected recesses, for should it impinge upon any projecting angle in its course the current will at once be destroyed and will not enter the parts beyond. In all cases where disinfection of the upper nasal cavity is required, the following practice is recommended:

First cleanse the mucous surfaces within reach with some simple alkaline spray. Follow this with a spray of adrenalin, the adrenalin spray to be repeated until the upper parts have been successively opened and the whole way to the roof of the nasal cavity is clear. Then, and not until then, and guided by a clear demonstration of the parts by a good light and a nasal speculum, the dichloramine-T spray can be thrown to the remote upper parts which most stand in need of it, and the disinfection of the region made complete. While it may be said that this method, thorough as it is for the nose, does not reach the nasal sinuses, it nevertheless has proved more practically effective than any other method of which we know.

The disinfection of the vault of the pharynx may be secured by first applying the adrenalin to the soft palate and the lateral walls of the pharynx, thus facilitating the complete introduction of the spray.

Used in the strength of 2 per cent., the solution of the dichloramine-T is seldom irritating. In the case of stronger solutions it may become so, producing a sensation of smarting or burning. This is easily obviated by reducing the percentage of dichloramine-T of the solution to as low as 1 or even ½ per cent. Otherwise than this, the oil is well tolerated and free from any injurious effect. For its application in the form of spray, an atomizer must be used which will throw the spray *in all directions.* It should be made of some medium which will not be acted upon by the chlorine, and the compressed air should be supplied from a good condenser.

Theoretically, the most complete possible exposure of the affected areas should permit the best contact of the disinfectant. Practically, this is found to be true, as proved by the speedy success of the treatment, two or three applications often sufficing to sterilize the parts. Where success is delayed, there will usually be found enlargements of the tonsils or of the adenoids, or marked obstruction of the nose. In such cases, after a reasonable number of local treatments have been given without avail, the removal of the offending lymphoid tissue or suitable attention to the nasal cavity must be considered.

Dr. Stanton A. Friedberg, in his excellent theses (Trans. Am. Laryngological Ass'n, 1917 and 1918), has ably set forth the value of the operative treatment in diphtheria carriers, and concludes with the

*Gordon and Flack, *Brit. Med. Jour.*, Nov. 18, 1916.

statement: "When the bacilli persist in spite of any local treatment beyond a period of three to four weeks, the removal of tonsils and adenoids is the most effective treatment and the most uniformly successful that has yet been proposed." The same treatment has been found true in the case of meningococcus carriers.

In cases where no obstruction exists or where for any reason the immediate removal of adenoid enlargements is not advisable, the dichloramine-T chlorcosane solution seems to offer the best hope of a speedy cure. If, as is the fact, complete disinfection can be accomplished in uncomplicated cases with as few as three, two, or even one treatment, the superiority of the method over others is beyond question.

As to the relative merit of the application of the oil solution as compared with the inhalation method, the results seem to show that the former is more prompt in its action and that in uncomplicated cases the number of treatments required is far less. Again, an important advantage is the simplicity of the outfit. An inhalation room could hardly be established at any but a hospital of some importance and at considerable expense, while its apparatus is sufficiently complicated to require expert care. My desire is to offer a method so simple in itself as to be readily carried out by the average practitioner, with the aid of apparatus inexpensive, durable, and clean, very compact of form and light of weight, and therefore conveniently available for use under all circumstances of medical practice, whether at home, in the hands of the practitioner and the health officer, or in the various branches of hospital and field service of the army and the navy. All that is necessary for this is:

1. The recognition of the principle upon which success absolutely depends, namely, that in order to carry the dichloramine-T chlorcosane solution to the chief foci of infection these foci must first be thoroughly exposed, as described above.

2. The application of the dichloramine-T solution by means of a properly constructed spray atomizer, the air current being supplied if possible from an air condenser and not by means of an india-rubber handball.

3. The devotion of time and painstaking care to the effective carrying out of the treatment.

I have personally used this method sufficiently to believe that in it we have a means for overcoming infections of the upper air passages which is more simple, safe, prompt, and successful than any hitherto known.

40 East Forty-First Street.

SHELL SHOCK AND OTHER WAR NEUROSES.*

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL NEUROLOGY, COLUMBIA UNIVERSITY.

THE subject of this talk is shell shock and other war neuroses. The term shell shock has been used to so great an extent that I think you will form a much better conception of the condition if you classify all of these war conditions under the one heading of war neuroses. Shell shock, then, is a war neurosis. *A war neurosis is a nervous disorder, without necessarily a physical disease or injury, the cause of which is modern warfare.* An other definition of it is hysteria, occurring in a person free from hereditary or personal psychoneurotic antecedents, but with a mind more responsive to psychical stimulus than the normal.

There are many types of symptoms—among them are hysteria, tremors, paralyses, confusion, stupor, temporary blindness, temporary deafness, temporary loss of speech, hallucinations, nightmares, states of anxiety, gait disturbances, headaches, vertigo, insomnia, and sweat disturbances.

To understand shell shock one must form a conception of a distinct disease, just as one would understand pneumonia, typhoid fever, or a broken leg. It is a disease which is, however, nervous in origin, nervous in symptoms, and nervous in its general course. Bear in mind that these nervous conditions are just as much complete diseases as are the medical and surgical conditions. Shell shock, therefore, must be regarded as a condition which has a history, a cause, a period of incubation, a course, a set of symptoms, a prognosis, and treatment. I think if you will start with this conception that you will find the study of shell shock simpler, easier, and more interesting.

The history of shell shock is as old as that of some of the most ancient diseases. When this war began a great many of the English and French writers began to describe a new condition and to give a new name to the condition. As time advanced and the war progressed men's minds began to crystallize and settle down so that in a very short time the medical men who had described this new condition recanted what they had said and realized that in giving the name shell shock to a certain set of symptoms, they were simply dressing an old idea in new words. The symptoms of shell shock are not limited to the present war, nor to the Civil War, nor to the Revolution. In the history of Ancient Rome and Greece you will find that in the days of Xenophon and Cæsar the soldiers engaged in battle complained of the same symptoms as those which are to-day described under the name of shell shock. Again, if you will reflect that shell shock is the result of unusual conditions, of violence, and of noise, you will realize that the same symptoms occur in our modern functional conditions. There were many of these cases in the Civil War, but at that time they were not classified as neurotic or as functional conditions, but rather were they called organic disorders; it was thought at that time that these conditions were produced by the impact of the air from the passing shell against the body. In other words, it was thought that impact with the concussion produced by a large moving force of air was able and did cause organic changes in the brain, the spinal cord, and the nervous system. The result of such conditions was, in the opinion of the medical mind of that day, actual paralyses, real choreas, and organic tics.

It was not until the war between Japan and Russia that a conception of shell shock and war neuroses became manifest. The present war has magnified the cases, has enlarged this idea, and

*Read before the M. O. R. C. at Camp Mills, N. Y., May 16, 1918.

now it is recognized that there are an innumerable number of functional conditions which formerly were thought to be organic.

The next point which I wish to bring out is the *similarity which the war neuroses present to the hysterias and neurasthenias of civilian life.* The two conditions are practically alike. The man on the street will react in the same way as the man on the battlefield. The woman caught in the elevator shaft, and the engineer who goes through the wreckage of his train, whether these two be physically hurt or not, will present the same psychic condition as the soldier in the trench.

Several years ago Dr. Pearce Bailey wrote a book on accident and injury. The book came out long before the present war, yet, if you will glance over the pages and read some of his neuroses and hysterias you will find a very strong similarity to the cases of the present day which are described as shell shock.

The fact that this war differs so from all that have preceded it both in magnitude and type, in methods of warfare, and in organization, makes it inevitable that it should produce what at first was thought to be a new medical condition. This accounts for the appearance of the term shell shock. The title is catchy. It arrests and holds the attention and this accounts for its permanence. Although I prefer to use the word war neuroses, shell shock has caught the public fancy, and shell shock has come to stay. In our time there will be many cases. Bear in mind that it will not be a waste of your time to understand the subject of war neuroses because not only will you see many cases in this war, but you will see many cases after the war. The American people are especially a neurotic race. They are, in my opinion, becoming more and more so. We live in an intensely artificial way and in the next ten years we shall probably be more artificial, so that neuroses and hysterias will be more frequent. You will see many, both during and after the war.

The first question which will suggest itself to your mind is: *why should there be so large a proportion of shell shock cases as occur in the present war?* The reasons for this are numerous. In the first place, the war is on a larger scale than any preceding it; in the second place, more is at stake than in any previous contest; in the third place, there are more prolonged offensives and battles. Again, the human race is more neurotic than it has ever been. One must recognize at the start that the armies of the world show an enormous percentage of constitutional inferiors, of neurasthenics, of psychopaths, and of men with markedly neurotic temperaments. Here in New York there is a very large population which is Hebraic in race, and as you know, there is no more marked attribute to the Hebrew than a neurotic temperament. Therefore, the present emergency which this country finds itself in is one which is the result of two important factors which go to produce the war neuroses, namely, the enlarged battlefield and the suitable soil in which the neurosis may develop. It is an emergency which presents the two important factors of heredity and environment; factors both of which are admirably suited to bring about the war neuroses of the present day.

Not only do there exist these two important factors, but also there occur numerous subordinate causes, all of which tend to accentuate the two principal ones. I want to call your attention to some of these subordinate factors because of the importance which they occupy in bringing about the condition. Never before in the history of the world have soldiers been subjected to such horrible sights, never before have such large numbers been destroyed, mutilated, and never before have such unusual and terrible means of warfare been waged. The modern machine gun, underground trench life, the presence of vermin and rats, are all factors which have tended to make the environment more unusual, more abnormal, and one which would more than ever destroy the normal temperament as well as the neurotic. In this war the length of the battles, extending, as some of them do for several weeks, has rendered it difficult for soldiers to obtain regular rest, has rendered it difficult for them to escape great fatigue, and lowered vitality. Therefore many factors have upset the individual.

I am trying to convey to you the fact that the present war is waged under different conditions than any preceding, and that the soldiers engaged in it have been obliged to lead more unusual and abnormal lives. That, in addition to this, a large number of soldiers engaged in the present war are more highly civilized and therefore more highly neurotic than soldiers of preceding generations; and, again, trauma received by the soldier, whether it be physical or mental, is greater and more damaging than any such trauma received in preceding wars. Incidentally, these are reasons why such great care should be exercised in eliminating the conscripted men.

If possible, the number of war neuroses should be held down to as small a number as possible. Therefore, the neurologist and psychiatrist must play an important part as eliminants before the final army is chosen.

The great difference which occurs between the war neuroses and the neuroses of the civilian is that the civilian has periods in which he can sleep, periods in which he can rest, periods in which he can have those about him whom he loves, to divert his mind and help him to get control of his nervous system. The soldier in the modern war has none of these aids. He is continuously under fire and he is continuously among those who are subject to the same environment and the same shocks.

I listened, only a short time ago, to a very interesting analysis of the figures of the conscripted men. from a neurological point of view. Lieutenant-Colonel Bailey of the National Army, gave us a very interesting lecture at the Academy of Medicine, in which he collected the statistics of the men in the army. It was very surprising to see how few had organic nervous diseases, how low down in the list ranked alcohol and addiction, how small were the figures for syphilitic infections, and how enormously great were the statistics of constitutional inferiors, psychopaths, and mild dementia præcox cases. I cannot remember exactly his figures, but it seems to me that the percentage of constitutional inferiors was something like 20. With so large a

percentage as this and with such tremendous shell fire as we read of, how could it be otherwise than that traumatic functional conditions should develop and predominate?

Causes.—The causes of the war neuroses can be classified under two major headings: (1) Mechanical, (2) Psychological.

(1) The mechanical heading does not necessarily mean a blow to the individual, because war neuroses occur in many cases in which the soldier is not wounded. It means the jolt—that is to say, the shock which the individual received from the noise, from unusual conditions, or from the destruction of everything about him. Secondly, there is the fatigue. Very few cases develop that have not previously been tired out, exhausted, cases in which the general system was considerably below par. As predisposing causes which can be placed under the heading of mechanical, I am going to place the excessive use of alcohol, nicotine, and the infectious diseases. The excessive use of alcohol and tobacco serves to lower the vitality and therefore acts as a predisposing cause. It superinduces fatigue; it renders the nervous system less liable to withstand unusual conditions and shocks; when the jolt comes the patient develops a neurosis.

(2) The psychological. The four headings under which I have subdivided the psychological causes of the war neuroses are: (1) acute situations, (2) suggestions made by the physician, (3) the environment, (4) personal problems. The acute situations which may develop and precipitate a neurosis are such conditions as bad news from home, death of wife or mother, and distressing letters from sweethearts.

There is considerable responsibility to be assumed by the physician who suggests removing a man from the front line and sending him to the rear. Even the doctor's tone and manner of handling a soldier at the front is fraught with responsibility.

The environment is probably the most important of the three factors. The presence of vermin, wet clothes, fatigue, hunger, and horrible sights, all tend to disturb a man's equilibrium and act as predisposing causes of bringing about war neuroses.

Symptoms develop as to time and place very considerably. Apparently this is dependent upon the personality of the individual and the extent to which he is neurotic. Some cases may develop in the camp before the soldier has started for the front, others may develop back of the line, and finally many develop at the front. The usual time is just before the attack and practically very few develop during hostilities. The onset may be gradual or sudden. When it is gradual, and this is the most frequent method, it is possible to foresee the approach of the attack. The patient becomes restless, somewhat morose, and does not do his work in the usual way. His increased nervousness may continue for several days.

In order to understand the symptoms of any condition, whether it be medical or neurological, organic or functional, we must have a distinct classification under one or two headings, and then enumerate the symptoms in the order of their importance under each heading. I should classify the symptoms of shell shock under the two main headings of *physical* and *mental*.

I. The *physical symptoms* may be placed under the headings of (*a*) motor symptoms; (*b*) special sense symptoms; (*c*) symptoms connected with the autonomic system.

The motor symptoms include tremors, tics, paralyses of the various extremities, and gait disturbances.

The special sense symptoms include those symptoms which may arise from a perversion of any one of the five senses; blindness, in connection with the sense of seeing; partial or complete deafness in connection with the sense of hearing; anesthesia or paresthesia in connection with the sense of touch or feeling; and absence or perversion of the senses of smell and taste.

The symptoms of the autonomic system may be classified under palpitation of the heart, shortness of breath, cold, clammy hands and feet, purplish and mottled extremities, and profuse sweating, to the extent that a man's clothing may be soaked.

The motor symptoms, as I have said, include tremors, tics, paralyses, and gait disturbances.

The *tremors* can be divided into two classes: (*a*) typical, (*b*) atypical.

The typical tremors are those which resemble the well known tremors which are characteristic of the nervous system. The atypical tremors are irregular, disorderly, and in no way resemble any of the well recognized types of tremors.

The typical tremors are imitative, whereas the atypical ones appear to be wholly imagined by the patient, that is to say, they originate in the mentality of the sufferer. These atypical types are more apt to affect all of the muscles than any group or extremity. In general the physiognomy expresses indescribable terror. There is rapid heart action and marked flushing, alternating with pallor in the face. The various secretions of the body, such as the sweat, the tears, the saliva, and the urine, are increased. The type of the tremor is distinctly coarse, with an extensive excursion, and resembles more the twitching characteristic of chorea than the classic tremor. The movements are initiated by any slight stimulation, even by the touching of the patient by the bed clothes, or by a violent noise, as the slamming of a door. Everything seems to suggest the noise of the battlefield.

The determining factor is evidently the emotional sphere which has been upset by the shells and which is in such a disordered condition that anything suggestive of a shell will precipitate a complete disorder of the motor system. The typical tremors resemble those which are characteristic of the organic nervous diseases and can be classified as such. There are the pseudo-paralysis agitans type, multiple sclerosis type, toxic type, exophthalmic goiter type, cerebellar type, and general paralysis type.

The onset of these tremors at times varies. The most common onset is following a slight loss of consciousness. A man may be in the trenches, at a listening post, or resting in one of the cantonments, when suddely a shell falls at a short distance. He is thrown into the air, falling back upon the ground with a loss of consciousness. So soon

as he recovers consciousness, either at the evacuation hospital or in the ambulance, he is seized with a marked tremor involving his entire body. The more unusual manner is for the tremor to occur immediately after the explosion without the patient losing consciousness. In the still rarer cases the condition may present itself only after an interval of hours or days. This has been described by Charcot as the phase of meditation.

There is still one other type in which the tremor does not present itself until the patient has gotten up and is practically cured of his wounds. In these instances, the tremor is of the nature of a reminiscence of the preceding shock and can therefore be classified under the heading of retrospective emotions. Many of these tremors are aggravated by inspection, by the appearance of the medical adviser, and by attention. It is evidently a disturbance of the emotional element which is at once stimulated by contact, touch, the appearance of someone, noise, or any unusual event. In other words, there is an abnormal state of the emotional sphere which is easily thrown into abnormal function by the stimulation of any one of the five senses.

The *tics* are of two types, tonic and clonic. The latter, clonic tic, or spasmodic movements, is far more common than the former. So far as their distribution is concerned, those affecting the head are the ones which one sees most constantly. They take the form of head nodding of either affirmation, or lateral movements of denial. Again, there may be a spasm of the face, either onesided or bilateral. Another common type of tic is that in which there is a shrugging of one or both shoulders. These tics vary greatly in their development, course, and termination, offering many variations, so that it is difficult to give you a typical picture. The duration is probably unusually long and the course of the tics varies greatly, dependent on the early diagnosis and subsequent care.

The *paralyses* which occur in shell shock are probably the most frequent and important of the neuroses. They simulate very much the organic paralyses and may be either spastic or flaccid. Probably the flaccid type is the more common, just as in the hysterical paralyses we get almost invariably the flaccid type. There are monoplegic, hemiplegic, and paraplegic. The etiological factors in each one of these paralyses are very similar. Like most of these motor disturbances in shell shock, the paralyses occur in those cases where a great shock has been received, but no wounds. It is, therefore, a form of cerebrospinal emotion. They may present themselves immediately after the traumatism or not until the patient has recovered consciousness, again illustrating what Charcot described as the phase of meditation.

Two points I want to call to your attention in regard to the paralyses are, first, that they are very frequently preceded by pain. Thus, monoplegia of the leg may be preceded several days by pains in the knee and ankle. Secondly, the point at which the traumatism strikes the patient has no bearing whatever on the appearance or the location of the paralyses, thus, a blow at the shoulder may very readily produce a paralysis of the leg, and just as much of the leg as of the arm. The arm is more often affected than the leg. The trunk is sometimes affected, but the face and tongue rarely. The physical signs which accompany the hysterical paralysis of shell shock are identically like those of hysterical paralysis seen in civilian life, that is to say, the member hangs flail-like, the reflexes are normal, and the muscular tonicity is equal on both sides. The superficial reflexes also remain normal. Bear in mind, especially, that Babinski's reflex is never present in an hysterical paralysis. Therefore, the symptoms which accompany the paralysis of shell shock are variations in sensibility, loss of power, trophic disturbances, vasomotor changes, and electrical changes.

The hemiplegia is the least common of the three types, the monoplegia being the most common. In addition to these paralyses, there occur, but less frequently, paralyses, circumscribed in character, affecting one particular portion of the body—thus it is not uncommon to have a complete paralysis of the foot, of the hand, or of certain portions of the body. These paralyses will be more clearly pictured to you if I use the word contracture. The contractures of the trunk are very remarkable and interesting. In some the trunk is at right angles to the body, in others it is bent to one side, in still others the patient stoops forward or backward, remaining in that condition for an indefinite time.

Gaits.—The fact that there are disturbances of gait is proof that a particular patient may have an emotional state which is not itself active, others a state of suggestibility, in which there is fixed an upheaval or disturbance of the function of walking. Like the tremors, the gaits may be typical or the reverse. The typical gaits are those which imitate the classic, ataxic, hemiplegic, drop foot, and choreiform gaits. There are four or five atypical forms which are difficult to describe and which do not resemble any particular type of walking.

There is also the condition known as astasia-abasia. This, as you probably know, is a condition, in which, when lying down or sitting, the patient can use his legs or feet in any way he desires and is able to perform any sort of motion, but when he stands up and attempts to walk it is impossible for him to take a step, and he has to push or drag his legs and can only progress with the aid of a cane, and then only for a short distance.

There are also instances in which the patient is typically lame and limps or drags one foot. These patients pretend to be lame because they suffer, whereas in reality they suffer because they are lame.

Special Sense Disturbances.—The sensory disturbances can be divided into two large headings—the pains and the anesthesias.

The *pains* are of course the more important because they interfere more with the usefulness of the patient, because they are more lasting, and because the patient who suffers from them demands relief. The pains involving the lower extremities, the legs, are the most frequent, the most easy to feign, and the most difficult to control. The onset of these pains is variable. They may be sudden and spontaneous in their onset, or they may follow some slight illness and then persist, or they may follow directly a shock or blow. The previous

condition of the patient seems to play but little part in their onset, and they appear in soldiers of all ages, from the youngest to the veterans, in those who are apparently without a neuropathic taint, as well as in those so predisposed.

It is best to adopt the following classification and put them down as: (1) Pains in the legs, by far the most frequent; (2) pains in the arms, the rarest; (3) pains of the trunk and spine, fairly frequent; (4) pains of the neck and head; (5) visceral pains.

The pains of the lower leg are of several types—sciatic, coxalgic, and the neuritic type. There are also pains which appear only when the patient walks or makes use of the legs. The pains in the arms are much less frequent and usually unilateral. The characteristics of these hysterical pains are that they are illogical in their appearance, irregular, and erratic in their localization. Thus, there may be pain of the hands, whereas the patient has a complete paralysis of the entire arm. The distribution of these pains does not follow any nerve, plexus, or any sensitive point. They are mobile, and shift from day to day in their localization. They are inconstant, sometimes producing slight, and sometimes severe sensations. There are of course no physical signs which accompany the appearance of these pains. The pains in the trunk, and those of chest and abdomen, take the form of pleurisy, intercostal neuralgia, and appendicitis.

The *anesthesias* are far less important than the pains because they are not observed by the patient and only appear following a medical examination. There is of course not sufficient reason for placing the patient in a hospital. It is difficult, well nigh impossible, to say anything about the onset of these conditions, because you will readily realize that they are not perceived by the patient. There may be small spots or vast zones. Whether it is anesthesia or analgesia, hyperesthesia, or hyperalgesia, it is rare to find them occurring separately, and they usually form part of a complex syndrome in which motor troubles predominate.

The Autonomic Symptoms.—The symptoms referable to the autonomic system, that is to say, referable to the parts of the body that are not under voluntary control, are very common. There is no soldier in the trenches who does not have, to a slight extent, some of these symptoms. They are: palpitation of the heart, profuse perspiration, restlessness, and sleeplessness, without any organic lesion. Another prominent symptom which occurs in connection with these is the "all-gone sensation" which one feels in the abdomen. This is largely due to a change in the distribution of the blood supply under the stimulus of fear.

II. The *mental symptoms* of shell shock and other war neuroses are numerous, variable, and unless systematically arranged, confusing. Ames in his book says that they vary from the extremes of the ideational to the emotional. I think you will find it easier, however, if you divide them into two large groups, and call one the mental and the other the emotional.

Under mental I would place five symptoms, and under emotional five. I am going to enumerate these various symptoms to you and then I am going to take up each one in turn and say a few words about it. If you are taking notes I would suggest that you simply put down these five headings: (1) Speed of thought; (2) sluggishness of thought; (3) confusion; (4) memory disturbances; (5) anxiety.

Under emotional symptoms: (1) Restlessness; (2) crying; (3) general discontent; (4) great irritability; (5) phobias; (6) fatigue.

Let us now take up each one of these symptoms in detail and for a moment talk about it. By the speed of thought, I mean exhilaration, the same condition which presents itself in the manic stage of manic depressive or circular insanity, and in acute mania. As you probably know, in these conditions the patient has a constant flow of ideas. He is rapidly changing from one subject to another, never completely finishing one. His speed of thought is also accompanied by rapidity of movement, a constant desire to do things, great mental stimulus, simulating, only much more so, a state of mind following a small ingestion of alcohol.

The second symptom is sluggishness of thought, and is just the reverse. It is known as depression and is the symptom which follows the depressed stage of circulation insanity and is the leading characteristic of melancholia. In this condition there occur great mental inertia and great physical inertia; the cerebration is slow, new ideas come with great difficulty, and old ones can hardly be completed or their plans executed. Procrastination accompanies the condition and the patient may sit in front of a clock and let hours go by without having carried out a single plan.

The third symptom, that of confusion, arises somewhat as a complication resulting from either the exhilaration, the depression, or the mental fatigue. It is especially noteworthy following marked periods of either one or the other. It becomes worse as the condition advances and is most harassing to the patient and distressing to the onlooker. The sufferer becomes confused as to his environment and surroundings, especially confused as to his actions. He is at a loss to know what he should know, what action he should take, and he begins to wonder if he is in any way following out the right course.

The fourth symptom, that of memory disturbances, is one which may take the form of loss of memory either for recent events or for those of several years back. I should say that it was more apt to take the place of recent events. It may be one of many grades, ranking from a slight impairment to one which is complete. The memory may be intact for events which happened previous to the shock, while at the same time the patient remembers nothing in regard to events occurring subsequent to the shock. To compare this with civilian life, to emphasize the resemblance of the shell shock suffered by the soldier and the shell shock suffered by the civilian, I am going to tell you of an instance which has recently been brought to my attention. A lady lost her husband, who dropped down dead. She attended his funeral, put on mourning, and arranged all his affairs. Two days afterward she became exhilarated, then depressed, and a week later absolutely denied that he was dead. She became confused and her memory for the two days following his death was com-

pletely lost, whereas she remembered everything of her early life up to the day of his death.

Anxiety, the fifth symptom, while I place it last, is one of the most important and one of the most common. It resembles the well-known anxiety condition seen in civilian life which we call the anxiety psychosis, a psychosis which is particularly evident in people of advanced age. The patient suffering from anxiety becomes a pessimist, sees no hope in anything, considers that his life is over, that the world is to be destroyed, and that all his efforts have been wasted and will come to naught.

Treatment.—War neuroses are curable. The treatment is a success from the medical point of view but a failure from the military standpoint. The mere fact of this statement will serve to emphasize the condition, to bring to your minds more closely just what is a war neurosis. These patients can be made well, but may have a recurrence of the same condition. The rule is that the patient who has suffered from shell shock or a war neurosis inevitably under the same conditions and environment will suffer a second attack. Here is another reason for the importance of eliminating these patients before they reach camp, and especially before they reach the battle front.

To understand the treatment of shell shock you must understand psychology. It is eminently a problem in psychological medicine. Dr. Salmon, who has been abroad and who has studied this question at length and in detail for the United States Government, puts the matter very aptly when he says that the first step is a careful study of the individual, an understanding of the personality. He means by that that each case is a law unto itself, and to be successful one must thoroughly understand the idiosyncrasies, the peculiarities, and the unusual trend of mind of the patient. The man who intends to treat shell shock must understand human nature and must be able to analyze and classify his individual patient.

There are several forms of treatment, several aids which can be brought to your assistance. I shall enumerate these and then discuss them. They are: (1) Suggestion; (2) Re-education of the patient; (3) Persuasion; (4) Hypnotism; (5) Occupation; (6) Hydrotherapy; (7) Electrotherapy. In attempting the first of these, suggestion, one must grasp the mentality, the caliber, and the possibilities of the patient. You can readily see that when you adopt suggestion as a method of treatment, you will have to use different language and make different appeals to the commissioned officer than that which you would use to the private; different to the man of education than to him who is ignorant; different to the man who has human feelings and affections than to the man who is cold, unresponsive, and without ties.

The next point is to lay especial stress on the incident which precipitated the neurosis. It may have been a shell explosion, or it may have been a crisis in discipline. The method of talking will be somewhat different in each case. During this psychological examination the physician must be careful not to disclose any too great chagrin or surprise at the revelations made by the patient. Suggestion means causing the patient to acquire confidence in his recovery, confidence in his physician, enthusiasm, interest, and desire to get well. Similar cases may be cited in which recovery has taken place. A general optimistic view of the whole situation should be imparted. Suggestive measures may be outlined whereby the patient may help with his recovery. In all of these the suggestions must not surpass the mental caliber of the patient. If this is done not only will you waste time and energy, but you will inspire confusion where confidence should exist. Suggestion must, of course, have a proper environment. The country is superior to the city and there is no doubt that suggestion near the battle front is more dramatic and more convincing than that which is undertaken hundreds of miles away with a hospital ward as the scene. It is in the acute cases that suggestion is especially valuable. When suggestion has failed, when the case has become chronic or of long duration, the next step is re-education of the patient.

Reeducation means to teach the patient the use of the apparently lost faculty. If it is that he cannot walk, take him by the arms and teach him each step, each motion of the foot and leg as you would a child. If it is that he cannot speak, begin with sounds, syllables, words, and finally sentences. Reeducation takes patience, a phlegmatic temperament, and time. I do not believe that every man is capable and competent to undertake the reeducation of nervous patients. One must have great resources of time, energy, enthusiasm, and interest, and no outside disturbing factors. Drills and physical exercises are part of the re-education of some cases, and from here it is but a step to occupation.

Nothing helps a nervous patient more than a suitable occupation. Again I refer to Salmon, who divides the occupations into bed, indoor, and outdoor. There are certain pastimes which the patient, who is bedridden from his neurosis, can follow. These are basket weaving, net making, and even knitting. For those who are up and about and yet unable to go out there are all the little occupations which can be done about the hospital and house, such as making the surgical dressings, sand papering, polishing, woodcarving, carpentering, bookbinding, cigarette making, and many others which your ingenuity and good sense may suggest. The best occupations of all, however, are those followed out of doors, such as farming, gardening, wood sawing, and wood chopping. Gymnastic exercises are, of course, always of value, but bear in mind that the practical and productive occupation is of much more importance and aids the patient both physically and mentally to a much greater extent than the non-productive. Therefore, as soon as possible, do away with that form of occupation which is only suggested for the purpose of killing time and assign to the patient an occupation which is productive, practical, and one in which he can see evident results. Nothing helps these patients more than an occupation which they feel is necessary and is doing some good and accomplishing some results. Among these occupations none is more valuable than swimming. You can readily see that when one of these patients is in a tank of water he has to make an effort in order to keep afloat, and nothing is better for the paralyses and gaits. This is espe-

cially so because all of these conditions, whether organic or functional, are less severe in water than in the air. You know that the treatment of locomotor ataxia can be, to a great extent, helped under water more than in the air.

Persuasion is so much akin to suggestion and the time for this discussion is so limited it seems to me that I can pass it over with a very few words. Persuasion, to be of value, must also take into account the type of patient, and must be carried out with skill.

Hypnotism is of some value. Personally, I am opposed to hypnotism, principally because it injures the morale and the mental control of the subject. If I hypnotize one of you there is no doubt that I exercise a certain control over you which I can exercise at any time I desire.

Hydrotherapy has a distinct value. It is especially good when applied in the form of spinal douches, when it exerts the double effect of shock and tonic to the nervous system. It is of more value when it is used in the form of the hot bath for the rigid backs, the contractures, the tics, and the paralyses. But both patient and physician must recognize its limitations. Too many people are apt to think that both water and electricity, when applied to a nervous patient, can be a cure-all.

Finally, in the treatment of these conditions, the environment of the patient is essential. The patient with shell shock and war neurosis ought not to be allowed to lounge about a sunny yard or to remain idle in a hospital ward. His mind should be constantly occupied as well as his body. He must be enthused with the idea that cure is possible and that cure is essential. He must be taught that he is still of value in the world and that if he cannot go to the front he can still go back to civilian life and there be of service. Shell shock produces a condition which is essentially infantile and childlike. The patient must, therefore, be treated as a child, led along, and slowly but steadily induced to think that he is better.

I think that it is the opinion of most men who follow these conditions that many of the present cases of shell shock will recover when the war is over. The important point, however, now is to reduce the cases and therefore there should be men skilled in this work, psychiatrists and psychologists, as near the front as possible who can take these cases and by the methods of suggestion, re-education, persuasion, hydrotherapy, and occupation exert an immediate cure. Many cases have been cured in a very short time. Of course probably most shell shock cases would be better away from the battle line, but bear in mind that if this is done to a great extent you will encourage many of the milder nervous cases to acquire and feign the war neuroses.

Drugs are of very little value in treating shell shock. Digitalis has practically no effect on the pulse rate. So far as using bromides in quieting the patient, their result is not satisfactory, as they serve rather to depress than quiet. Veronal is probably the only drug which has the slightest effect. It does help the insomnia and does induce sleep. It is needless to add that there are no conditions in shell shock in which opium is warranted.

41 East Sixty-third Street.

THE MEDICAL TREATMENT OF EXOPHTHALMIC GOITER.*

By James Francis Rice, A.M., M.D., F.A.C.P.,

Buffalo, N. Y.

If you will allow me tonight the luxury of an etiological theory merely as a working basis, it will help us, I believe, in the review of what must be done for the unfortunate patient and it will furnish a working basis for the relations of internist and surgeon in the solution of the thyroid problem.

Crile's theory of the kinetic drive' has been, I believe, probably the most helpful of recent contributions to the study of this problem; and, with your kind indulgence, I wish briefly to recall the main features of this theory.

The kinetic drive, according to Crile, is the excessive excitation of the kinetic system. The kinetic system is the brain and the muscles, together with the suprarenals, liver, and thyroid.

"The organs," says Crile, "which from moment to moment vary and control, accelerate and retard the driving force of the *brain* are the *suprarenals*, the pacemaker of the kinetic system is the *thyroid*, and the final act of adaptive energy transformation is performed by the *muscles*."

The activators of the kinetic system are: physical injury, heat and cold, emotions, infection, autointoxication, pregnancy, excessive food, poisons, and others.

Crile tells us, "perhaps the most typical of the kinetic diseases is exophthalmic goiter. In exophthalmic goiter the kinetic system is driven by a continuous activation, because in this disease there has been established a pathologic interaction between the brain and the thyroid, whereby the threshold of all stimuli is kept continuously low * * *. The principal phenomena of exophthalmic goiter are identical with the leading phenomena of any other kinetic drive of a corresponding degree of intensity, and may be duplicated by fear, anger, sexual excitation, physical exertion, overwork or acute infection. Conversely, many of these activations cause hyperplasia of the thyroid. Thus fear, anger or sexual emotion may cause temporary enlargement of the thyroid; there is hyperplasia of the thyroid in pregnancy, in chronic infections, and perhaps in intestinal autointoxication as well."

The recognition of a disease as a process rather than a condition calls not so much for a remedy as it demands a program.

Viewing the process of exophthalmic goiter as one form of the kinetic drive, the problem of its control becomes the question of blocking the effect of the activators of the kinetic system. This may be accomplished quickly and easily, but only temporarily, by the use of opium, which raises the threshold of effective stimulation of the kinetic system. Similarly the diminution of the blood supply to the thyroid or the removal of part of the gland, serves to restore normal equilibrium by diminishing the supply of activating substance delivered by the thyroid to the blood-stream. The difference

*Read before the Surgical Section of the Buffalo Academy of Medicine, April 3, 1918, as part of a Symposium on Goiter.

between these two methods of control suggests their different use in the treatment of the disease. Should we not restrict the use of opium to the paroxysmal periods of the disease process, and should we not consider surgery curative because it effects an internal readjustment? The surgical intervention which breaks the vicious circle cannot, however, accomplish the patient's restoration to health, unless the favorable situation it produces is made use of for the prolonged medical care of the patient's mental and physical hygiene. There must be accomplished, not only the anociation of the patient, that is, the blocking of the effect of the activators of the kinetic system, but also the removal of these excitants, in order to prevent re-establishment of the same vicious circle. The patient's trouble is originally a medical problem; and, if the surgeon's work is successful, it becomes again a medical problem. Does this not suggest earlier recourse to surgery, with more definite acknowledgment of the chief responsibility of the internist?

A rough classification of cases of exophthalmic goiter for the purposes of this paper, may be made as follows:

(1) *Incipient* Graves' disease, in which the diagnosis must be made by the family physician or internist;

(2) *Advanced mild cases*, including cases even of marked exophthalmos and very prominent goiter, in which the disabling symptoms occur in brief paroxysmal periods;

(3) *Rapidly developing severe* cases, and

(4) *Advanced severe* cases.

Incipient cases of Graves' disease should be rested and environmental readjustment made. Hygiene should be corrected, diet should be supervised, autointoxication and any focus of infection should be remedied; but the fundamental requirements are rest and environmental readjustment. For example, a girl of sixteen; ambitious, overworking at school, active in outside interests, and harassed by her responsibilities at home, was not much helped by dropping a few of her studies at school, or by general hygienic measures, but she was promptly relieved of symptoms by the return of her father. The father had been away for months, leaving the patient as the eldest daughter in actual charge of the house, because the mother is mentally defective. This patient was evidently driven by anxiety, one of Crile's "activators." She was undoubtedly a fit case for the care of an internist. The case is cited as illustrative of the correctness of the principle of readjustment, and not because its course is typical. Usually the process of restoration to health takes much longer. There is often evidence of intestinal toxemia, there may be focal infection.

An *advanced mild* case of exophthalmic goiter can sometimes be carried along with a minimum of treatment and helped over the crises by a few doses of morphine. I remember the case of a woman of about 50, a widow with a family of grown children, who sent for me on two or three occasions when she had been made worse by some emotional excitement, responding very satisfactorily to a half-grain of morphine in the course of 24 or 36 hours by mouth, given in solution with the direction that a teaspoonful (containing gr. 1 24) be taken every hour or two until she felt better. (She was not told what she was taking, and the drug was dispensed by the physician himself, who left this limited amount for her to use either within a few hours or "spread out" as she might prefer.) This case is cited as an extreme instance of how little need of a physician seems to be felt by some of the most slowly developing cases.

A *rapidly developing severe* case should be seen at once by both the internist and the surgeon for this reason: if delay is caused by the use of any other than surgical measures, the integrity of the myocardium is endangered. Of course, rest and environmental readjustment should be carried out as far as possible; but may we not consider that in this group of cases such procedures are properly to be undertaken after surgical intervention has improved the prognosis? Before operation medical measures are needed by way of preparation; but, when careful medical preparation is not feasible, an early operation seems to have less risk than a delay of weeks or months with the resulting inevitable impairment of cardiac reserve.

An *advanced severe* case should probably be considered a neglected case. The outlook for relief is equally dubious, whether medical or surgical measures are recommended. There is so little left to work with. Heart, liver, and kidneys have been too severely punished.

Does it not seem, therefore, as if we should follow our early diagnosis with the prompt summons of the surgeon? To block the vicious circle, should not the thyroid be thrown promptly out of gear, so that the careful application of recognized measures of medical care may restore to complete health a much larger percentage of our cases? If the kinetic drive be interrupted by the surgeon's work upon the thyroid, its control must still be continued for weeks and months, and the patient, whose cooperation in this program of medical care is essential, will be encouraged to recovery by the confidence developed by the knowledge that his heart has not been exhausted nor the rest of his kinetic system worn out.

Diet.—The accelerated metabolism which is characteristic of exophthalmic goiter makes necessary the closest attention to the problem of nutrition. Some authorities tell us that the hyperthyroid case should have a low-protein diet, while others emphasize the need of forced feeding and a diet rich in proteins. May we not consider diet one of the unsettled problems of the disease? For practical purposes the prominence of either an intestinal toxemia or a glycosuria should often prove to be the determining factor.

Certainly there will have to accumulate a much greater volume of recorded observations of metabolism in Graves' disease before we can generalize upon the dietary requirements of this disease. Meanwhile the acute cases will have to be fed whatever they will retain. A milk diet will continue to be our sheet-anchor.

Water.—All authorities apparently agree in the advice that the patient should drink water different from that of the locality in which he lived during the development of the disease.

Climate.—It has been suggested that the proper climate for patients suffering with exophthalmic

goiter must be cool and dry, with sunshine and no fogs, only moderate winds, and an elevation of from 1500 to 2000 ft.[2] At any rate, a change of climate from that of the patient's home is apt to be of value, for the sake of a different water supply.

Psychotherapy.—There are few diseases in which the patient is so dependent upon the medical counselor for optimism and the will to survive. Fatigue is a cardinal symptom of exophthalmic goiter, and peace of mind is a fundamental feature of successful treatment.

Rest.—Rest must precede operation; it must follow operation. The opinion of an eminent surgeon[3] that 90 per cent. of all goiters can be so improved by medical treatment as to make operation unnecessary was probably based upon observation of the effect of rest, for rest is the common element in all the various forms of treatment that have proved successful. (That opinion, by the way, is Kocher's, indorsed by Charles H. Mayo.) Rest in bed is inevitable in the severe cases. If improvement is accomplished, the comparative rest secured by a change of scene must be ordered. The theory of the kinetic drive helps us to remember how indispensable to success is rest—rest of mind and body.

Exercise and Gymnastics.—We must be careful in carrying out the essential rest of the patient that we do not neglect the business of first passive and then active exercise, and later perhaps gymnastics under careful supervision. This is a very long and tedious chapter.

Hydrotherapy.—The use of the various applications of water certainly has its place in every complete scheme of treatment of so long a process as the uphill climb to health of these patients. In the acute stages the sedative effect of water-applications is of the first importance, and it is probable, if hydrotherapy were more frequently employed then, that the problem of nutrition would be less troublesome. In the long process of recovery, hydrotherapy has undoubted value in its stimulant and tonic phases.

Massage and Non-surgical Mechanical Measures.—These procedures have a share in the restoration of muscular tone and strength, which is so large a part of the program of recovery, after the acute stage has passed.

Heat and Cold; Light and Electrotherapeutics.—Under this head there should be mentioned the use during the acute stage of an ice-bag or Leiter coil over the thyroid, over the heart or in both places.

Electrotherapeutics and the use of light have, of course, their part in the coaxing of the patient back to health and strength.

Radium.—There are a few who seem to be encouraged to believe in this agent for the destruction of thyroid tissue. Abbe of New York, Turner of Edinburgh, and Wickham of Paris have made contributions to the study of this comparatively recent addition to our resources.[4] I think you will agree with the view, however, that any new procedure in the treatment of exophthalmic goiter must be tested through a series of years before it can have any standing as a remedy for the disease.

Roentgen Ray.—It is possible that a field for the use of the Roentgen rays in Graves' disease will be found in those cases of retrograde thymus following strumectomy, especially in young patients, of which Halsted has reported six cases with favorable results.[5] Halsted quotes Capelle, assistant to Garré, as finding thymus persistens hyperplastica at autopsy in 95 per cent. of fatal cases of Graves' disease. Halsted's cases had failed to recover after extirpation of the thyroid, and promptly got well after Roentgenization of the thymus.

Drugs, Organotherapy, Vaccines, and Serums.—We come to the side of our problem which presents so many different aspects to the student of medical history. It would be an unwarranted trespass upon your good nature and kindly endurance, to attempt even an outline of the changing customs in the use of chemical and biochemical agents that have been employed in times past and present in the treatment of exophthalmic goiter.

Each of these many remedies has had its successes and its period of popularity. To each has been attributed some part of the large percentage of recoveries that would probably regularly occur in the absence of all treatment. It undoubtedly is because of the usually favorable prognosis in this disease that we still find in the text-books lists of "things to be tried."

At present we may not conclude the consideration of the medical treatment of exophthalmic goiter with the reflection that, just as opium is the agent of temporary relief in the paroxysmal crises of the slowly developing cases, so surgery is probably the agent of internal readjustment which should be promptly and early invoked in the rapidly developing cases for the release of the threatened heart from the vicious circle of a process which, though sure in most cases to come to an end of itself, inevitably and inexorably, while it lasts, injures the heart.

If this point of view be generally adopted, we shall care less about recovery from goiter, but much more shall we strive for the protection of the endangered myocardium. We shall be unwilling to allow a disabling disease to run its unabbreviated course, and we shall have fewer nominally recovered patients carried off by the accidents that are fatal in the presence of myocardial degeneration.

EXPERIMENTAL TEST WITH COPPER AND POTASSIUM CYANIDE IN TUBERCULOSIS.

By M. J. FINE, M.D.

NEWARK, N. J.

CHIEF OF TUBERCULOSIS CLINICS OF NEWARK BOARD OF HEALTH
ASSOCIATED EXAMINING PHYSICIAN FOR THE ESSEX MOUNTAIN SANATORIUM AT VERONA, N. J., AND
CHIEF OF THE TUBERCULOSIS CLINIC OF THE BETH ISRAEL HOSPITAL, NEWARK, N. J.

Inasmuch as Dr. Koga's cyanocuprol has been brought to the attention of the medical profession as a curative agent in tuberculosis, and has elicited favorable comment in some of the medical journals, particularly in the article of George H. Evans in

the October 6, 1917, issue of the MEDICAL RECORD, I deemed it my duty to avail myself of my opportunities of reporting the preliminary findings after giving a fair trial of this remedy so liberally furnished me by the Kitasato Institute.

This report is based upon twelve cases divided as follows: Six pulmonary, three pulmonary with laryngeal involvement, one kidney case, and two skin cases. Tubercle bacilli were found in all the cases excepting those of the skin. Six of these cases were in a sanatorium during the treatment. All the other cases were treated at home. The remedy was administered intravenously at intervals of two weeks in the pulmonary, laryngeal, and kidney cases and every week in the skin cases. After each injection, the patient was confined to bed for six days; no other medication was given during the course of treatment, except an occasional dose of codeine in those with an unusual racking cough; all the other directions contained in Dr. Koga's circular were strictly adhered to.

Some of the cases received decreasing doses, others increasing doses; the kidney case received the same dosage during the entire course of treatment. This course of treatment was followed as outlined by Dr. Otani.

The preparation is claimed to be composed of the salts, copper cyanide, potassium cyanide, and calcium chloride, used in doses varying from 4 to 24 milligrams.

CASE I.—Hubert D., American, white, age 28, clerk. Admitted to the Verona Sanatorium August 10, 1916. Father and mother dead. Cause not known. The disease dates back five years when he was operated upon for mastoid trouble. Denies venereal disease. Does not drink. Complains of weakness, cough, shortness of breath, and a slight hemorrhage occasionally after coughing. Weighs 124 pounds. Temperature 99° A.M. to 100° P.M. Pulse 90. Did not improve while in sanatorium. Sputum positive. Poorly nourished, anemic; has extensive bilateral involvement; moist rales at both apices extending to the third rib anteriorly on the right side. Probably a small cavity on the left side at the angle of the scapula. No complications.

First injection, March 31, 1917, 4 c.c. of copper and potassium cyanide.

Second injection, April 14, 1917, 4 c.c. No reaction. Temperature as usual.

Third injection, April 28, 1917, 4 c.c. No reaction. Lost 1 pound.

Fourth injection, May 11, 1917, 3 c.c. No reaction. Lost ½ pound.

Fifth injection, May 26, 1917, 3 c.c. Slight hemorrhage next day.

Sixth injection, June 6, 1917, 2 c.c. No reaction. Lost 2 pounds.

No change in the condition of chest. Patient feels the same. Sputum still positive.

CASE II.—Eugene P., American, while, male, age 34, metal worker. Admitted to sanatorium December 6, 1916. Mother and brother died of tuberculosis; wife also has the disease. Patient had pneumonia and pleurisy two years ago and was subject to colds. Present disease started about eight months ago, with a cough and pain in the chest. Weighs 120 pounds. Temperature 98.3° A.M. to 99.2° P.M. Sputum positive. Patient is somewhat emaciated. Chest very little involved. Expansion limited, with dullness and bronchovesicular breathing on the right side. A few rales after coughing, extending from apex to second rib. Rough breathing on left side, a few rales after coughing.

The first injection was given March 31, 1917, 4 c.c.; the second on April 14, 1917, 4 c.c. On April 20 he sustained an injury of the head and went to the hospital. Returned with same condition in chest.

Third injection was given May 6, 1917, 2 c.c.; three days later complained of pain in stomach.

Fourth injection on May 20, 1917. No change in weight, chest or sputum.

CASE III.—Edward F., Irish, white, age 31, advertising agent. Admitted to the sanatorium January 24, 1917. Father died of tuberculosis. Patient had pneumonia five years ago. Present condition started three year ago with a cough, followed by a hemorrhage. Drank moderately. Denies venereal disease. Temperature 99° A.M. to 101.3° P.M. Sputum positive. Physical examination showed the patient quite emaciated; disease moderately advanced; retraction above and below both clavicles, dullness extending from apex to fourth rib on right side, and hyperresonance on the left side. Moist rales over both sides of the chest; cavernous breathing at the angle of scapula on the left side. No applications. Was losing weight gradually since he entered the sanatorium.

First injection, March 28, 1917, 4 c.c. in reaction. Gained 1 pound between time.

Second injection, April 14, 1917, 4 c.c. Lost 1 pound.

Third injection, April 28, 1917, 4 c.c. No change.

Fourth injection, May 11, 1917, 3 c.c. Lost 2 pounds.

Fifth injection, May 26, 1917, 2 c.c. Lost 1 pound.

Sixth injection, June 6, 1917, 2 c.c. Lost 1½ pounds.

Patient died November 16, 1917. Sputum was positive until death.

CASE IV.—Elsie V., Italian, white, age 14, school child. Admitted to the sanatorium December 19, 1916. Family history could not be obtained. Had pneumonia some time ago. Present disease started with a cold, followed by a hemorrhage while the patient was on the way to this country. Examination shows patient well developed and fairly nourished. There was muscular rigidity on both sides of the chest, limited expansion on the right side, few rales after coughing at the apex on the right side, bronchovesicular breathing on left side. No complications. Sputum positive.

First injection, April 14, 4 c.c. No change.

Second injection, April 29, 4 c.c. Lost 2 pounds.

Third injection, May 11, 3 c.c. Lost 1 lb.

Fourth injection, May 26, 2 c.c. Lost 1 pound.

Fifth injection, June 9, 2 c.c. Lost 1½ pounds.

Condition much worse, weaker, has night sweats and chills. Rales extending on the right side as far as the base.

CASE V.—Chester C., Italian, white, age 16, schoolboy. Admitted to Verona Sanatorium for the second time October 8, 1916. Father and mother died of tuberculosis. Two brothers are in the sanatorium now. Had pneumonia twice. Present condition started a year and a half ago as a result of pneumonia. Examination shows patient's general condition fairly well developed. Physical signs of an active tuberculosis extending from the apex to the lower edge of the shoulder blade on the right side. Moist rales on the left side and cavernous breathing between the third and fourth ribs on the same side. No complications. Tubercle bacilli numerous.

First injection, March 31, 1917, 4 c.c. No reaction.

Second injection, April 11, 1917, 3 c.c. No reaction.

Third injection, May 26, 1917, 2 c.c. Felt weaker.

Fourth injection, June 9, 1917, 2 c.c.

Patient has grown much weaker since the first injection; lost 7 pounds. Chest and sputum the same.

CASE VI.—Felix S., Irish, white, age 37, single, leather worker. Father died of tuberculosis. Had nephritis about three years ago, otherwise was never sick. Had been a heavy drinker. Denies venereal trouble. Present disease started about eight months ago with a cough, weakness, loss of weight, and hoarseness. Coughing. Examination shows patient quite emaciated. Disease in the chest moderately advanced, both sides involved, moist rales over the entire right side and on the left side as far as the fourth rib. Larynx on examination showed marked infiltration of the epiglottis, erosions of both cords, and a thickening at the interarytenoid space. Sputum positive.

First injection, February 28, 1917, 4 c.c.

Second injection, March 14, 1917, 4 c.c.

Third injection, March 28, 1917, 4 c.c.

Patient claimed he felt better and could eat better right after the first injection, and after the third injection he lost four pounds and was much weaker; by the advice of his regular physician cyanocuprol was discontinued.

Case VII.—Bessie N., Hebrew, white, age 23, single, dressmaker. Admitted to the sanatorium June 6, 1916. Patient complained of hoarseness and pain in the chest. Family history negative. Was never sick before. Present disease started with a considerable hemorrhage three and a half years ago. General condition of patient fair. Examination of chest shows both apices infiltrated. Rales after coughing on both sides extending to the third rib. Examination of larynx shows infiltration of entire epiglottis and ulceration of the right half of the cord. Sputum positive.

First injection, April 21, 4 c.c. No reaction.
Second injection, May 4, 4 c.c. No reaction.

She lost two pounds and requested to discontinue injections. Chest and sputum the same.

Case VIII.—Stefan F., Russian Pole, white, 34 years, metal worker, married. Habits good. Family history negative. Was never sick. Had been six months in the sanatorium, leaving there six months ago. Present disease started a year ago with hoarseness and shortness of breath. Physical examination of chest shows disease moderately advanced, involvement on both sides. Moist rales over the entire right and partly the left side. A probable cavity at the angle of scapula on right side. Examination of larynx shows erosion of right cord with infiltration at the right ventricle. Sputum positive.

First injection, February 21, 4 c.c.
Second injection, March 8, 6 c.c.
Third injection, March 23, 6 c.c.

Patient stopped coming. After the second injection he complained of losing weight and not feeling as well as before. Chest was the same and sputum positive.

Case IX.—Harry H., American, white, single, 36 years, electrician. Brother died of tuberculosis. Was never sick in his life with the exception of gonorrhea. Present disease started nine months ago, when he noticed he was losing weight and was getting weaker. Was since then in a sanatorium and felt much better. Examination shows patient's general appearances good. Is only six pounds below his normal weight. Physical examination shows infiltration at the right apex; a few rales after coughing; harsh breathing and prolonged expiration at the left side; sputum positive.

First injection, February 21, 6 c.c. No reaction.
Second injection, March 7, 8 c.c. No reaction.
Third injection, March 21, 10 c.c. No reaction.
Fourth injection, April 4, 12 c.c. No reaction.

No change in chest, general condition, or weight. Patient refused further treatment.

Case X.—Richard M., Italian-American, white, age 19, student. Referred to me by Dr. Miningham for treatment with the diagnosis of tuberculosis of both kidneys. Family history negative. Two years ago was operated on for a double inguinal hernia; since then has lost about twenty pounds. Complains of a dull pain in the inguinal region and a boring pain at the dorsal region. Examination of chest negative. Cystoscopy and catheterization show that both kidneys are involved. Examination of urine found tubercle bacilli and a great deal of pus.

First injection, March 28, 4 c.c. No reaction.
Second injection, April 14, 4 c.c. Lost 1 pound.
Third injection, April 28, 4 c.c. No change.
Fourth injection, May 11, 4 c.c. Lost 2 pounds.
Fifth injection, May 26, 4 c.c. Lost 2 pounds.
Sixth injection, June 6, 4 c.c. No change.

General condition slightly improved. Less frequent urination, and on examination of urine tubercle bacilli could not be found. No decrease in the amount of pus.

Case XI.—Evelyn H., colored, age 8 years. Referred to me by Dr. Wallhauser with diagnosis of lupus vulgaris. Mother died of tuberculosis. Patient was never sick before. Present disease started five years ago as a small tubercular eruption on the middle of the left cheek. The tubercles gradually ulcerated and resolved, leaving scar tissue. New crops appeared and spread, developing the same ulcerations as the original, until the entire side of the face was involved. Examination shows patient well developed, chest negative.

The lesion involving the left side of the face about the orbit extending down the cheek presents an aggregation of ulcerating tubercles, outlining a cicatrized area corresponding to the original site from which gradual extension occurred.

First injection, March 3, 2 c.c.
Second injection, March 11, 3 c.c.
Third injection, March 20, 4 c.c.
Fourth injection, March 30, 5 c.c.

Patient did not show any change and it was advised by her physician that she be put on tuberculin.

Case XII.—Julia S., Austrian Pole, white, age 28, single. Referred by Dr. Wallhauser with the diagnosis of lupus vulgaris. Family history negative. She was never sick before. Started four years ago as a small tubercular eruption at the middle of left cheek. These tubercles gradually ulcerated and spread peripherally until the entire cheek was involved. Examination of the patient shows general appearance good, chest negative. Lesion consists of numerous apple-jelly tubercles with pale granulation between, extending from the angle of eye to the ear above and the angle of the mouth below.

First injection, March 7, 6 c.c. No change.
Second injection, March 14, 6 c.c.
Third injection, March 21, 4 c.c.

Ulceration became more pronounced and started to spread very rapidly. Injection discontinued.

Conclusions.—I did not notice any focal reaction in any of the cases. Pulse, temperature, sputum, and chest were practically running the same course as they were before the treatment was instituted. The weight (as to loss or gain) was also the same. One of the pulmonary cases was always subject to slight hemorrhages and these occurred during the time the injections were given. None of the patients complained of pain at the seat of the injections, nor in any other part of the body, during the trial with the remedy.

The kidney case shows some improvement. The patient was sent to the country two days before starting the treatment, and therefore it is very hard to determine whether the improvement was due to the change of climate and rest, or to the treatment.

In only one case was noticed a psychological effect after the first injection, the patient claiming he felt better and could eat better immediately.

From the experience with the above remedy, I cannot subscribe to the favorable reports that have been advanced from this treatment. On the other hand, I did not notice any detrimental effects. I therefore would say that a further trial may be justifiable.

THE STIGMATA OF ABRAMS IN HEREDITARY SYPHILIS.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

SAN FRANCISCO, CAL.

My contributions to the Medical Record[1] have engendered so much correspondence on the part of physicians desirous of learning more concerning the "Electronic Reactions of Abrams,"[2] that the writer is prompted to place on record, several new signs heretofore unrecorded which are frequently encountered in hereditary syphilis.

Electronic Reactions—Sufficient evidence has accumulated warranting the assumption that these reactions may be accepted as diagnostic of syphilis and to enable the cognoscenti to differentiate hereditary from acquired syphilis. Geo. O. Jarvis,[3] found the electronic tests of Abrams positive in nearly 100 per cent. of syphilitic affections hereditary or acquired and he comments as follows: "In the diagnosis of syphilis, the Wassermann reactions were not positive in every case in which the elec-

tronic tests showed the presence of syphilis and in which the clinical history and therapeutic results showed beyond reasonable doubt that the Wassermann reaction was at fault."

W. J. Caesar has published a report of 192 blood

FIG. 1.—Auricular sign.

tests made at the State Hospital, Stockton, Cal., (March 6, 1918) using exclusively the 'electronic reactions." The specimens were submitted by physicians of the hospital including the pathologist, under rigorous conditions, with the object of eliminating any previous knowledge on the part of the executant relative to the disease or the patient from whom the blood was derived.

The specimens included syphilis (congenital and acquired), tuberculosis, carcinoma, syphilis and tuberculosis, and syphilis, tuberculosis, and carcinoma. In the latter instances, the specimens of blood on the same paper were derived from different patients. The electronic reactions were absolutely correct in 186 instances among 192 specimens of blood submitted for examination (3 very small specimens were not examined, making 189 actually examined).

Reference to the foregoing is made with the object of emphasizing the correlation of the signs to be cited in hereditary syphilis. The value of a positive Wassermann test in hereditary syphilis may be seriously questioned considering the beneficial results of antisyphilitic treatment in cases with a negative Wassermann. Syphilitic infection must always be considered in all chronic diseases. Stoll[4] avers that in "late" hereditary syphilis, the patient may present no sign of syphilis but a single obscure symptom which may be so distressing that more or less complete invalidism results. Jarvis[4] quotes Kaskell, who observes, that while a positive Wassermann can be elicited in about 40 per cent of the wives of paretics and tabetics, yet only a small percentage of their children yield a positive reaction to that test.

"Familial syphilis" may be suspected or predicated if any of the following statements are made as to the cause of death in relatives: (1) Tabes, (2) Paresis, (3) Aneurysm, (4) Apoplexy (before 50 years of age), (5) Cardiorenal disease, (6) Headaches (not relieved by the usual means), (7) Nervousness (without obvious cause), (8) Rheumatism (obscure), (9) Tuberculosis in several members of the same family. Hereditary syphilis according to Fournier, strongly predisposes to tuberculous infection later in life.

Ubiquity of Syphilis.—The electronic reactions demonstrate the ubiquity of syphilis and emphasize the dictum of Fournier, that general pathology should be made a mere annex to syphilography. That the world is becoming civilized is debatable, but that it is syphilized is unquestionable.

I have recently found that when the voltage of the radioactive energy of the blood of any individual is augmented about 1300 per cent., the electronic reaction of congenital syphilis is always present. The writer has shown experimentally (MEDICAL RECORD, Oct. 6, 1917) that the spleen is the usual nidus for the luetic virus. This heterodox conception is sustained by William J. Mayo, in his Carpenter lecture (Oct. 18, 1917) as follows: "Hibernation of spirochetes in the spleen permits luetic reinfection of the body."

Sabouraud[4] makes a practice of applying the Wassermann test in all dubious affections in children, and observes that all who do this will be appalled at the findings. The German diagnostician avers:

> "Was man nicht diagnostieren kann,
> Sieht man als n' syphilis an."

In free translation, the latter may be expressed as follows:

> When your diagnosis goes amiss,
> Always think of syphilis.

It was said of Ricord, who was a confirmed skeptic as to the morality of the race, that he would have submitted Diana to treatment with his mineral specifics and prescribed a course of blue pills for the vestal virgins.

Fournier observed that 98 per cent of the children of syphilitic parents are syphilitic. The electronic reactions show that they are all syphilitic.

The tale of syphilitic parents may be inscribed as follows: sterility, stillbirths, miscarriages, abortions, progeny dying in infancy of marasmus, meningitis, convulsions, etc. Hochsinger's observations, embracing 208 children of syphilitic parents, show that 89, or 43 per cent, had some affection of the nervous system. Among these, which is in vivid

FIG. 2. Digital sign.

contrast with my observations as will be shown presently, in only 6 was the Argyll-Robertson pupil demonstrable . Congenial syphilis is unfortunately identified with its manifestations at birth and we are liable to forget that it may not develop until

adolescence or late in life. Congenital is practically a replica of acquired syphilis.

Certain anomalies in physical structure have been sufficiently emphasized and attention is here directed to new signs in heredosyphilis.

Argyll-Robertson Pupil.—This sign is regarded by many as positive proof of nervous syphilis. No attention has been directed to the slow or sluggish pupil (reflex to light) which the writer finds to be fairly constant in hereditary syphilis, irrespective of implication of the nervous system. It may be equally a unilateral or bilateral phenomenon. Although the light response may be fairly good in the first test, subsequent tests show its rapid exhaustion, a phenomenon almost as important as a partial Argyll-Robertson.

Auricular Sign.—This consists of a distinct ridge (Fig. 1) running from the antitragus downward toward the lobule. Localized elevations of the skin in the region in question must not be accepted as evidence of the auricular stigma. It may be unilateral or bilateral. In the Da Costa Edition of Gray's Anatomy (Fig. 752), there is a picture of the external ear which reproduces my auricular sign.

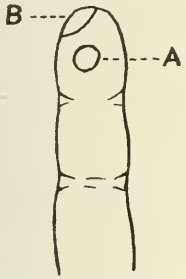

FIG. 3.—Vasomotorial sign. A and B, sites of pallor in heredosyphilis; B, site of pallor in acquired syphilis.

This must be due either to a faulty execution of the artist or to the selection of a supposedly normal ear. The auricular sign is fairly constant in heredosyphilis.

The ridge is felt to be of cartilaginous consistency when palpated between two fingers. This morphological anomaly like all deformities of the auricle is essentially always the result of othematoma.

Digital Sign.—This consists of an incurvation of the little finger, usually implicating the second phalanx (Fig. 2) and is fairly constant.

Vasomotorial Sign.—If the subject faces the geographical west with feet on a grounded plate and the hands are elevated in proximity to a window, it will be noted after thirty seconds that a circumscribed pallor is demonstrable at the terminal phalanges of all the fingers, notably the little fingers, at definite points. At the palmar surface of the terminal phalanx and on the inner surface and extreme end in heredosyphilis (Fig. 3). In acquired syphilis, the circumscribed pallor on the palmar surface is not demonstrable but is seen in the other area only (extreme end). It is evident that mere elevation of the hands is productive of some anemia but the latter is universal and not circumscribed. The hands should be manipulated in relation to the light so as to bring the anemic areas into evidence if not readily seen. Other vasomotorial signs are present in other diseases and have been explained elsewhere.[7]

Ocular Pigmentation.—This sign is tentatively submitted and refers to an intense bluish pigmentation at the sclerocorneal juncture. While this pigmentation may be present in the norm, it appears to the writer that it is specially evident in heredosyphilis.

SOME OBSERVATIONS ON THE BLOOD SUPPLY OF THE UTERUS—WITH SPECIAL REFERENCE TO THE OPERATION OF VAGINAL HYSTERECTOMY.

BY HOWARD CRUTCHER, M.D.,

TULAROSA, NEW MEXICO.

CONSIDERING the immense importance of the uterine artery from a practical standpoint, it is surprising how small a space it usually occupies in anatomical literature, and of the small space that it does occupy much of what has been printed concerning it is unconsciously misleading. Anatomical works, whose unchallenged authority has become a proverb, describe the origin of the vessel with commendable precision, but its course after its arrival at a point near the uterine neck is not only the opposite of precise, but is befogged by demonstrable absurdities. Our first knowledge of this artery is more than likely to have been derived from a familiar old print in which the vessel is pictured as running a zigzag course, from below upward, to disappear in a more or less remote network of diminishing anastomotic threads. Some of which is true, but is only true in those cases in which the original course has been altered for the most definite of natural reasons. In the virgin subject no such course is pursued. In the virgin state the artery follows a tolerably straightforward course from its origin to a point at which its identity is blended through numerous branches with anastomotic twigs that spring from the ovarian artery above.

During the years of 1892-94, and occasionally in subsequent years, I performed a series of painstaking dissections of the uterus in virgin subjects, preserved careful notes covering my work, and meant to present my conclusions to the MEDICAL RECORD had not the loss of a valued letter file prevented my doing so. While I must speak from memory, I may say that in none of the subjects examined did the uterine artery describe anything approaching a tortuous course. And, indeed, taking a broad survey of the larger works of nature, is

there a single instance, in all the realm of general anatomy, in which nature prefers a sharp curvature to a gentler course, unless there be some definite purpose to be served by so doing? A series of zigzags appearing in the course of the uterine artery is no more in harmony with the general design of nature than are those gigantic bends in the channel of our great inland river, both arising in response to evolutionary forces and not because of a preexisting design.

In the case of a uterus that has undergone ripening and fruition, its principal artery presents a remarkable series of angles and curvatures, and for the simplest and most conclusive of reasons. At full term the artery traverses a course a foot or more in length. Within a few hours, possibly within a few moments, that course is reduced to a few inches, and the vessel is thrown of necessity into a series of folds by the forces of muscular contraction, precisely as a dangling rope, suddenly released from its fastening above, is hurled into loops by the power of gravity when it meets with a resisting surface at the end of its descent. Generally speaking, the uterine artery is relatively straight in the virgin subject, it undergoes great growth in length during the progress of gestation, and is thrown into unavoidable curves by the forces that promote fetal expulsion. This teaching is not only supported by strong natural analogy, but by the revelations of everyday practical experience. It is also in full accord with available konwledge and with common sense.

In a former paper (MEDICAL RECORD, April 13, 1918), I directed attention to the extensive lacerations that often involve the uterine tissues to an almost incredible degree. During the performance of hysterectomy I have frequently been impelled to express astonishment that spontaneous recovery should have followed childbirth in many such cases. Enormous tears sometimes extend laterally far into the broad ligaments and upward almost to the dome of the organ. In this great wreckage of soft tissues the uterine artery must escape dangerous injury for obvious reasons, or the patient would die speedily from bleeding. Subsequent processes of repair may involve the vessel in irregular masses and planes of scar tissue, which are likely to prove highly distressing at times to those who are impelled more by adherence to some mechanical ritual than they are by a wholesome respect for the principles of operative surgery. In all cases of laceration followed by extensive scarification it must be borne in mind that the artery is subject to the widest variations, both as to its supposed course and to its immediate relations.

The earnest and capable student of one branch of natural science will usually find the subject so stimulating and profitable that he will develop a keen desire to pursue the wider fields of general scientific knowledge. The great sciences of physiology and pathology, so vital to higher human welfare, are mere branches of those greater sciences of growth and decay, which are fundamental to all forms of life. Nature's resources are so immeasurably rich that prodigal waste is disclosed on every hand. Many of nature's general processes, however, are directed to the ultimate elimination of waste, and it is the true mission of science to penetrate the secrets of nature for a similar purpose. The mightiest convulsion of nature recorded in our national existence occurred in the heart of the Mississippi Valley in the year 1811, one notable effect of which was the reversal of the current of the great river for nearly an hour, that a vast chasm in the crust of the earth might be filled with water. But no familiar convulsion of nature, however violent, may justly be compared in magnitude with those alterations wrought in the human uterus by the processes of reproduction. From a small pouch of modest dimensions, the womb rises to the exalted dignity of the first of bodily organs. It is in perfect accord with nature's wasteful methods that so great an upheaval of human tissues should be productive of occasional irreparable damage. Muscular tissue, nerve tissue, blood-vessels, and connective tissue are involved in a common wreckage. The uterine artery, despite its extraordinary powers of resistance, does not always escape serious injury or possible destruction in such a turmoil of conflicting forces. Moreover, a vicious curvature in the nutrient artery, wholly trivial from a mathematical standpoint, ought to be quite as significant in principle to the pathologist as some stupendous freak in the course of a great stream is to the student of another department of natural science. Above all, it must not be taken for granted that the uterine artery pursues anything approaching an unalterable course from its source at the anterior trunk of the internal illiac until it disappears as a definite tissue somewhere within the variable folds of the broad ligament. Its variations are fully as pronounced comparatively as are those of other structures of the human body.

So far as uncomplicated vaginal hysterectomy is concerned the uterine artery ought no more to be involved in the procedure than the internal pudic is in the usual operation of perineal lithotomy. This vessel does not normally penetrate the uterine substance at any point, but flows through the loose connective tissue more or less distant from the body of the womb, and it may easily be pressed clear of all danger in the earlier part of its course by the finger of the operator, precisely as the ureter, the base of the bladder, and other structures of lesser importance may be dealt with in similar fashion. The splendid and harmonious design of nature does not admit of the coursing of a blood-vessel through the heart of muscular tissue, where its channel would be obstructed by the exercise of the normal functions of the muscle. Just why it should occur to any operator to plunge headlong into the needless and dangerous exploit of ligating the trunk of the uterine artery, when no such course is indicated, nay, when all the principles of rational surgical practice condemn it, may well be left to those who are more concerned with the observation of the letter of some ritual than they ought to be in the useful work of conserving human vitality. My conception of a classical hysterectomy is an operation pursued with the fixed determination of removing whatever tissues may threaten human life, with the least possible disturbance to those tissues that bear no such odium, and in the simplest, safest, and shortest

manner possible to human skill. If the uterine artery, or any other vessel, obstruct the main purpose of the operator, the artery must be sacrificed in the interest of sound surgical practice. But the whims of no operator, however celebrated, must be permitted to befog the luminous teachings of scientific surgery. The large and beneficent additions to the surgical art that have sprung from the labors of Kocher and Bassini are founded upon the clearest principles of natural science, and not upon the trivial likes and dislikes of individual students of natural principles. Art may assist nature by imitating her methods, but the highest art is admittedly that which most perfectly conceals its own existence.

Of all the dangers that arise from the operation of hysterectomy, unchecked bleeding stands preeminent; but the greater risk from this cause comes properly from branches above, and not rightfully from the main trunk below. The most dangerous field for copious bleeding will be found most probably in those dense upper bands of the broad ligament that are attached to the body of the uterus, when all reasonable danger to the main part of the uterine artery, the ureter, and other structures has been passed in safety. Through this part of the broad ligament the artery often lies in a series of loops, certainly none of which when severed can bleed when all have been securely compressed within the blades of a dependable clamp. To be more specific, after the main stem of the uterine artery has been driven from the field of operations, the danger of possible bleeding increases as we proceed upward, where a network of anastomotic twigs, quite variable in size, are generally found. The fundus of the uterus having been drawn well forward into the wound, the clamp is pressed home from below upward, closed securely, and well locked, where every movement is under the eye of the operator. I use the word clamp, being fully conscious of some of the absurd objections that have been raised against it, even by those who have never employed it. My preference for that instrument is based upon the reasons that it can with ease be employed in situations where no ligature can be applied, and generally in a fraction of the time that a man of the highest skill can tie a secure knot. The practical results of the operation speak for themselves.

This is not the time for a full consideration of vaginal hysterectomy, with its important complications, or even for a more extended word on the subject in hand. I am, however, gathering the essential materials for a more complete survey of this great topic, beginning perhaps with the work of the celebrated von Langenbeck, and presenting it in such form as may prove helpful to those who love science for its own sake and art supremely for its value in the saving of human life.

Mild Type of Typhus in Portugal.—Cases of exanthematic typhus have appeared in various parts of Portugal. They appear to be well scattered and thus far without mortality. The disease seems to have spread from the cities to the rural districts and a number of the cases were traced to a prostitute of Oporto. Several cases developed in the medical and sanitary personnel.—*El Siglo Médico.*

TESTING FACTS AND THEORIES OF HEREDITY.

By CASPER L. REDFIELD,

CHICAGO.

We observe that an unsupported thing will fall to the ground. By investigating the matter we find that there is a law, called the law of gravitation, which controls falling bodies. By studying that law, and by making some tests under it, we become satisfied that it is universal in its application to physical bodies, and that there is no such thing as an exception to the law of gravitation. But some person who is ignorant of the facts, or who wants to play upon the ignorance of others, might point to a rising balloon as evidence that the law of gravitation was a mere hypothesis not sustained by the facts. But, by reason of our knowledge of the fluidity of air, and the relative specific gravities of air and balloons, we know that the rising balloon is itself an illustration of the action of the law of gravitation. The contradiction is apparent and not real, and is due to the fact that the lighter of two bodies is visible to the eye and the heavier is not. When observation makes contradiction apparent, we may know that more than one factor enters into the problem.

It has been demonstrated that superior offspring come from older parentage, and that inferior offspring come from younger parentage. It may also be shown that inferior offspring come from older parentage, but it cannot be shown, except in a very qualified and limited sense, that we can get superior offspring from younger parentage. The term "parentage" here refers to the age of the parents at birth of children in several successive generations. "Superior" and "inferior" applied to offspring refer to their mental and physical powers and not to such things as the color of their hair or the shape of their toenails. It also refers to improvement or degeneracy continued through several generations. The fact that we may get both superior and inferior offspring from older parentage makes it clear that more than one factor enters into the problem. The statement that I have advanced the age of parents as the one overwhelming factor in heredity and evolution is a misrepresentation.

My friend says: "Mary is a superior girl. She is at the head of her class in school, and is a fine musician. She was born when her mother (Jane) was about seventeen years old; her mother was born when her grandmother (Susan) was about seventeen; and the grandmother was born when her mother (Nancy) was about seventeen. How about it?"

The question is a fair one and is entitled to a fair answer. That answer must necessarily touch upon methods by which facts are determined scientifically. But that touching must be both light and brief, as we cannot here give a treatise on scientific methods.

When we speak of Shakespeare, Franklin, and Humboldt as being superior men we are referring to completed life histories, and not to the relative standing of school boys. Shakespeare had "small Latin and less Greek," Franklin had almost no schooling, and in childhood Humboldt gave no in-

dication that he might later become one of the master intellects of the world. The fact that Mary is at the head of her class in school is no indication that she will become another Hypatia, Madame de Staël, Charlotte Bronté, or Harriet Beecher Stowe. The superiority ascribed to Mary is not sufficient for us to take her alone and compare her with the ages of her mother, grandmother, and great-grandmother. But I will not dodge the issue in that way. While there is nothing in the facts presented to show that Mary will become a remarkable woman, there is nothing to show that she will not. Some day, when this matter is better understood, the ages of these female ancestors will be considered as sufficient for us to say that Mary could not possibly become one of the remarkable women of the world, but we are not warranted in using that argument at the present time. We will simply concede that Mary is a bright girl and may become a woman who is rather more intelligent than the average woman in the community.

Mary is a bright girl, but the evidence presented by my friend does not indicate that she is any improvement over her great-grandmother, Nancy. In fact, she may be inferior to her great-grandmother. If we are to test the effect of ages of parents on offspring we must know whether there has been improvement or the reverse. When we pick such a monumental intellect as Sir Isaac Newton we know that there must have been an improvement, as it is out of the question that his ancestors several generations previously should have been his equal.

My friend gives the ages of Jane, Susan, and Nancy—female ancestors in three generations. But in the same generations, Mary had eleven other ancestors, the ages of whom are not given. These all have their influence on Mary's heredity, and for all that my friend says, the average age of the fourteen ancestors in three generations may be above the average for the community. Practically every pedigree extended for three generations shows some young parents in it, and these young persons may be at any places. The most that is set forth for Mary's pedigree is that there are unusually young persons in three-fourteenths of the places.

The age of parents is one factor in the problem. The other factor is the intensity with which Mary's ancestors were educated. When we know how hard those ancestors studied, and how many years that study continued, then we know how much they were educated. When we know how much they were educated, then we know to what extent their mental powers were developed by mental exercise, and the degree of that mental development is the real thing.

Mary is now a high school girl. If her mother had had as much as five years of schooling, then that mother had received considerable more schooling than was received by the average American child of the same date. If the grandmother received as much as four years of schooling, and the great-grandmother received as much as three years of schooling, then they also received more than the average children of their days received. The statement of my friend gives no information on this point for the three ancestors mentioned, and, of course, nothing for the eleven not mentioned.

When we take a large number of cases, properly classified with respect to some particular thing, we may concentrate on some particular point for the purpose of learning if that particular point is a factor in that particular thing. But when we have only one case, and want to measure it, we must know all of the factors, or at least, the principal factors. One of the factors in determining the weight of a body is its bulk, and one of the factors of bulk is length. But if we tried to determine the weight of a body by length alone we would find a kite string to be heavier than a cannon ball. In the case of Mary we have only part of the factors in one case, and, consequently, the question is indeterminate. We cannot say anything about Mary except that, with part of the factors small, she can not possibly be that kind of an extraordinary individual which is produced only when all factors are large. To show what effect age of parents has we must use entirely different data.

The eminent men of the world are superior individuals to whom our attention has been directed. The fact that our attention has not been directed to Smith of Jonesville is not evidence that Smith is lacking in qualities of superiority. It is well to bear that point in mind, as many persons go on the assumption that there is no existence to what they do not know. If we pick out several hundred of the most eminent men of the world we have a large number of persons classified under the head of intellectual power. With such a group we may direct our investigation to one possible factor, like the age of parents, and when we do so we find that these men were produced by fathers who averaged over forty years of age at the times when their eminent sons were born. We may also direct it to education as such, and when we do so we find that the eminent men not only came from fathers who were educated for many years, but fathers who were intensively educated.

But the most gigantic mass of reliable information on this matter to be found anywhere in the world is in the history and records of the American trotter during the nineteenth century. Analyzed and digested those records throw a flood of light upon what is necessary to bring about improvement in the human race. For example, the improvement in trotting speed was continuous and nearly uniform for a century of time. We have hundreds and thousands of animals which we may classify and which we may use to determine what factors enter into this improvement. We also have pedigrees in full for several generations for indvidual animals, and we may test these factors by applying them in individual cases. When we do these things we find that what we do for the development of the mental and physical powers of the race is exactly what we do for the development of the mental and physical powers of the individual. If a man wants to develop strong and powerful arms he must exercise the muscles of his arms. He cannot accomplish that result by studying law or wiggling his toes.

With trotters, improvement in trotting power from generation to generation came from sires and dams who developed their trotting muscles by hard trotting work before reproducing, and never came in any other way. Furthermore, the rate at which this improvement occurred in any particular line from generation to generation is proportional to

the extent to which sires and dams developed their own muscles by work before reproducing.

When Sir Isaac Newton said that bodies attracted each other directly as their masses and inversely as the square of the distance between them, he stated a mathematical proposition which was susceptible of direct proof or disproof. In saying that improvement in trotting powers from generation to generation was proportional to the extent to which sires and dams developed their own trotting powers before reproducing, I am stating a mathematical proposition which is susceptible of direct proof or disproof.

It is quite true that the amount of development acquired by exercise before reproducing cannot be determined exactly for any sire or dam, but it can be determined approximately in thousands of cases. When we make such determinations for the different animals in successive generations, we get the substantial equivalent of exact determinations. It is also true that there are some peculiarities in transmission which tend to obscure the relationship between parent and offspring, but when an improvement is traced through several successive generations, these are practically wiped from the slate. The thing to be noted here is that I am stating a thing which may be tested mathematically, and I am pointing to the records by which any one may verify my statements. In a way, such verification is simple, but it is not so simple that one can ignore half of the factors entering into the problem.

525 Monadnock Block.

Medicolegal Notes.

Hypothetical Questions—Evidence to Support—Reading from Books on Cross-Examination.—In an action against a school of osteopathy and a member of its faculty, who, it was alleged, while treating the plaintiff, negligently broke her sternum, what was said by the president and dean of the faculty of the school while making a diagnosis at the request of the defendant member, with reference to the condition of the plaintiff's sternum, ribs, etc., was admissible; it not being denied that such member treated the plaintiff as the agent and employee of the school. The statement of the defendant, while treating the plaintiff a day or two after the injury, to the effect that he was the cause of all the suffering, was admissible against him. It was held the trial court properly permitted the plaintiff to relate a conversation to the effect that, when she charged the defendant member with responsibility for her injuries, the accusation was not denied by him.

Every party has the right to put before the jury the scientific inferences properly deducible from such facts as the evidence tends to prove, and subject to the contingency that the jury shall find such facts to be as claimed. The rule is that the court will permit counsel to put to the expert, after his competency has been established, a question in which the things which the evidence adduced tends to prove, and which counsel claims to have proved, are stated as a hypothesis, and the witness is asked to state and explain the conclusions which, in his opinion, result. Then, if the jury should find that the facts assumed in the question have been proven by the evidence, they may use the technical information and instruction obtained from the expert in determining the ultimate facts; but, if they should find that the facts assumed in the question are not true, then, of course, the opinions based on them should be wholly disregarded.

It was objected for the defendant that the trial court erred in permitting counsel for the plaintiff to ask a medical witness the question as to whether or not Hulett (whom the witness had already testified was a recognized authority among osteopaths) in his book did not make the statement that "direct violence may cause depression, in which case there is likely to be a fractured cartilage, occasionally the row of cartilages on one side will be more prominent than those on the opposite." The objection was that it was "hearsay." Hulett's book, from which the statement was read, is a book recognized and used as a textbook by the defendant school for ten years, and the witness in question had so stated, and previously thereto had testified that according to the teachings of the defendant school there could be no fracture of the cartilage of the ribs. There was, therefore, it was held, no error in submitting the question. It is permissible in cross-examination to read to the witness statements contradictory to his opinions, found in books which he admitted to be authoritative, and to ask him to explain the contradiction. This practice is allowed on the theory that the books are referred to merely to test and discredit the knowledge of the witness.—Atkinson v. American School of Osteopathy, (Mo.) 202 S.W. 152.

Evidence in Malpractice Cases.—The Illinois Appellate Court holds that, in an action against a physician for damages for negligence in placing hot water bottles on the plaintiff's body during childbirth without protecting her body and limbs, the burden of proof of negligence is on the plaintiff. Evidence that the physician used a brass pin in opening a blister, caused by the use of a hot water bottle without adequate protection to the body of a woman at the time of childbirth, is inadmissible in such an action, where the only negligence was in negligently placing hot water bottles on the patient. The error was not cured by instructions of the court, where the only negligence charged was in negligently placing hot water bottles on the patient, and the purpose of the admission of the evidence was to inflame the minds of the jury. It was held that the defendant should be allowed to cross-examine a medical witness for the plaintiff, who attended the plaintiff after the injury and testified that on an examination he found the plaintiff's kidneys affected and that absorption from burns affects the kidneys, as to what diseases might have affected the kidneys. The gist of the action against a physician for malpractice is negligence and not the violation of the contract of employment.

The plaintiff, in such an action, must allege in her declaration her freedom from contributory negligence. Her failure to do so is not caused by verdict where an instruction directing a verdict and referring to the declaration is given that in effect informs the jury that it is not necessary for the plaintiff to prove that she was in the exercise of ordinary care. An instruction that the jury found for the plaintiff, then to enable the jury to estimate the amount of damages to the plaintiff for injury to her person it was not necessary that any witness should have expressed any opinion as to the amount of such damages, but the jury themselves must make such estimate from the facts and circumstances in proof was held to be misleading in referring to the damages as charged in the declaration, which enumerated physicians' bills, nurse hire, medicines, and being hindered and prevented from transacting her business affairs, as well as pain and suffering and weakness of body and mind caused by the injury. The damages for liabilities incurred and damages to her business affairs must be based on evidence of debts necessarily incurred and evidence showing the value of her mind and body are to be estimated by the jury in connection with their knowledge and experience in such matters.—Peters v. Howard, 206 Ill. App. 610.

Hypothetical Questions.—A party has the right to the opinion of an expert witness on the facts of the case as he claims them to be, and he may propound hypothetical questions assuming as proved all facts which the evidence in the case tends to prove.

It is a general rule that an expert witness should not be permitted to give his opinion upon the ultimate fact to be found by the jury. It is also another well-settled general rule that an expert may give his opinion upon any question within the realm of scientific knowledge. When the ultimate fact to be found by the jury is a scientific question, these two principles necessarily come into confusion, and one or the other must give way.—Sullivan v. Minneapolis, St. P. & S. S. R. Co., Wisconsin Supreme Court, 167 N.W. 311.

Military Medicine.

Medical Work in the British Army.—At a special meeting of the Toronto Academy of Medicine held on Monday, June 17, under the presidency of Col. A. Primrose, C. A. M. C. A., Col. Sir Arbuthnot Lane, R. A. M. C., gave a description of the remarkable plastic surgery and cosmetic work now being done in the special hospital at Sidcup near London. It was pointed out that face disfigurements were the worst, in that facial mutilations were so obvious. Men who had been wounded in the body or arms or legs returned to their families and received a hearty welcome, but in the case of face disfigurements it was an altogether different matter. The man who was thus disfigured often frightened his own children. Before the war plastic surgery was almost entirely unknown to British medical men, the only place in which Sir Arbuthnot had seen it was in Vienna. However, English surgeons had now learned the art thoroughly and this was demonstrated by the clear description given by the speaker of the remarkable manner in which the surgeons at Sidcup in collaboration with dentists, artists, and modellers in clay were able to build up or in many instances make a new face. It was described how the artist made a drawing of the face either from a photograph or from his inner consciousness as to what the face should be, after which it was modelled in clay and the parts lacking were supplied by bone, cartilage, and flesh taken from other portions of the body. Especially did the speaker lay stress on the bone grafting, drawing attention to the fact that while bone grafting in the extremities was a very uncertain procedure, because of the tendency to infection, in the head and jaw it was attended with quite extraordinary success. A "big chunk" of bone could be taken from the ischium, shaped and fitted into the jaw with no untoward consequences whatsoever. Emphasis was also laid upon the point that large pieces of epithelial inlay graft taken from the most suitable parts of the body could be used for the face with a very large measure of success. As for a lost eye not only could a very good substitute be supplied, but it could be made to move or rotate in so natural a manner that it was difficult frequently to believe that it was not a real eye.

Sir Arbuthnot Lane then spoke of the organization of the large military hospitals at Aldershot, the largest in Great Britain. His view as to the organization of such hospitals may be summed up in the statement that economy of labor makes for efficiency and such economy can only be gained by specialization. That is, each man should be given a certain line of surgical work to which he should wholly devote his time. It must be remembered that the ordinary medical practitioner is not called upon except in exceptional circumstances to do major surgery and therefore he is not a skillful surgeon. However, the exigencies of the war have rendered it imperative that all the available medical and surgical material of the entire medical profession of Great Britain should be called into service. Now it would be manifestly impossible, however apt to learn a man might be that he could cover the whole range of surgery, or even a considerable part of it in the comparatively short time at his disposal. But, if he specialized in a particular branch of surgery he might in a few months become competent and perhaps really proficient by thus concentrating his faculties. For example, an instance was cited of a general practitioner well endowed with this world's goods, who before the war had conducted his practice in a *laissez aller* kind of manner. When he was nailed to a specialty under the stress of endeavor and earnest hard work his hidden talent was discovered, and he has developed into not only a skillful operator but into one of the acknowledged authorities in Great Britain on genito-urinary diseases.

Col. Herbert Bruce, R. A. M. C., then gave a review of the medical and surgical work done at the front. With regard to the treatment of wounds it was pointed out that at the beginning of the war surgeons attempted to treat wounds on aseptic principles in the same manner as they had been accustomed to treat them in the hospitals at home. Under the conditions of war the results were exceedingly bad and for a time antiseptic treatment pure and simple held sway. This, too, was found to be unsatisfactory and various measures of one kind and another have been tested in order to discover a reliable means of combating sepsis. None of these has proved entirely successful. Wright's method has its advocates, and the Carrel-Dakin method is largely employed. However, it appears to have been demonstrated that effective drainage is of more consequence than the application of any antiseptic or of the use of any method for controlling sepsis. If a wound is thoroughly cleansed, however, it may be closed and frequently will heal by first intention. Attention was drawn to the fact that trench fever has been found to be infective, and that suspicion, almost amounting to certainty, has been directed to the body louse as the infecting agent.

Colonel Bruce held the opinion that the discovery that transfusion of blood is of the highest value in overcoming hemorrhage and hemorrhage plus shock was one of the most valuable results of the war from the medical standpoint. It was pointed out that not only fresh blood but citrated blood kept in cold storage could be employed for this purpose, and to Major L. Bruce Robertson must be given a great deal of the credit for establishing this mode of treatment. In the retreat of the Fifth Army a large number of bottles of citrated blood were captured by the Germans and it was suggested that it might be used by them to purify their own blood.

The great need for medical men was dwelt on and it was related how in the attempt to economize the time of the limited supply of doctors nurses were being trained to act as anesthetists. Especial praise was accorded to the work of the sanitarians and hygienists at the front and behind the lines. It was stated that at the present time there were only twenty-seven cases of mild typhoid fever in the entire British Army in France, a result due to inoculation and to efficient sanitary measures. The statement was made

by the speaker to the effect that while anti-typhoid vaccination was not compulsory in Great Britain, when the British soldiers were removed from home influence all opposition to the procedure seemed to vanish and vaccination was practically universal in the army in France.

Long Beach Hotel Taken for Army Hospital.—The Government has signed a contract for the use of the Hotel Nassau, at Long Beach, L. I. It is expected that the property will be taken over early in September. It is planned to use the building for a convalescent hospital for soldiers.

The Red Cross Organizes Overseas Communication Service.—The Atlantic Division of the American Red Cross announces that a communication service has been organized and that men are being sent to France in quest of casualty information. These men gather information concerning men in hospitals, write letters for them, and send news to the home folks. They also locate prisoners, seek the missing, and mark graves.

Casualties of the American Expeditionary Force.—The figures of the War Department, on July 12, show that up to that date there have been 1,629 men killed in action, 587 have died of wounds, 1,336 of disease, 501 have died from accident or other causes, 5,340 have been wounded in action, and 508 are missing. It is worthy of note that not as many men have died from disease as have been killed in action.

Mobile Hospital Units Ready to Sail.—Hospital units ready to sail or able to embark on two weeks' to a month's notice include base hospitals, evacuation hospitals, ambulance companies, railroad hospital trains, convalescent camps, and medical supply depots. All these are in addition to the regular medical department units. Fifty railroad hospital trains of sixteen cars each are on order in Europe or already delivered to the American Expeditionary Forces. Each of these trains has a capacity of 400 patients, with operating rooms, kitchens, etc. Each base and evacuation hospital comprises the personnel and equipment for a hospital with a normal capacity of 1,000 patients. Each ambulance company consists of 37 men and an officer and operates 29 ambulances. A convalescent camp is organized to care for about 10,000 patients and includes a 1000 bed hospital. Its personnel, as formed on this side, consists of 10 officers and 90 enlisted men. This is merely the medical personnel and will be augmented and later largely replaced by medical officers and enlisted men from among those convalescing. At these convalescent camps considerable reconstruction work will be carried on.

Wounded Soldiers in Scottish Woman's Hospital.—The Committee on Public Information, Division on Woman's War Work, states that fifty wounded American soldiers are being cared for in the Scottish Women's Hospital, Abbaye de Royaumont. America contributed $750,000 to the Scottish Women's Hospital, which was opened in December, 1914. The hospital started with 200 beds and has since increased the number to 500.

Elks Give Reconstruction Hospital.—Announcement was made at the fiftieth grand lodge reunion of the Benevolent and Protective Order of Elks, held in Atlantic City, on July 8 and 9, that a gift of a $350,000 reconstruction hospital had been made to the Government. Three weeks ago the cornerstone of a similar institution, costing $250,000, was laid in Boston. The second institution is to be located in New Orleans. The war relief commission of the Elks has charge of the distribution of $1,000,000 relief fund.

Women Health Officers for Munition Plants.—The Ordnance Department makes the announcement through the War Department that women health officers will be assigned to the munition plants to see that the women workers are kept healthy and their output of war material thus maintained at the peak of production. For the training of these inspectors an eight weeks' course of study is being given at Mount Holyoke College, South Hadley, Mass. The course is under Dr. Kristine Mann. The women taking the course are college graduates or women of equivalent technical education and almost all have had experience in dealing with working women. Many of the plants now have physicians and nurses to care for the workers when they are ill, but this work is to be done along entirely new lines, being entirely constructive and preventive.

Student Nurses Wanted for Training in U. S. Hospitals.—The Council on National Defense announces that 25,000 student nurses are wanted at once for training in American Hospitals. This call is for women between the ages of 19 and 25 years and is being issued jointly by Surgeon General Gorgas, Surgeon-General Rupert Blue, H. P. Davidson, chairman of the War Council of the American Red Cross, Dr. Franklin Martin, chairman of the General Medical Board, and Dr. Anna Howard Shaw, chairman of the Woman's Committee, Council of National Defense. The enrollment will begin July 29, and those who register will thereby be subject to call for training in the army nursing school or in civilian hospitals until April 1, 1919. The enrolling will be done by the Women's Committee of the Council of National Defense.

Four Schools Opened for War Cripples.—The first group of these schools has been in operation for some months and is known as the Red Cross Institute for Crippled and Disabled Men, at 311 Fourth Avenue, New York. This school teaches the manufacture of artificial limbs, linotype and monotype operating, mechanical drafting, and oxyacetylene welding. Similar schools are being organized in Chicago and St. Louis. The Smith-Sears bill recently passed by Congress provides an appropriation of $2,000,000 to be used at the discretion of the Federal Board of Vocational Education, which is working out plans in New York City. The law authorizes the commandeering of private and public institutions for the reeducation of crippled soldiers and sailors and, where necessary, the building of new schools.

Health of the Camps Excellent.—The weekly army health report, issued on July 11, states that health conditions at home camps are very satisfactory. Deaths during this week numbered 112, during the preceding week 81.

New Manhattan School Building Will Not Be Hospital.—The Board of Education of New York City has been notified by Surgeon-General Gorgas that the Government will not take over the new Manhattan Trade School for Girls as was announced some time ago. The reason for rescinding this order is that the arrangements for taking over the school were made without due authority. Surgeon-General Gorgas states that it is not the policy of the Medical Department to take over school buildings.

Ambulances Ready for Air Raid.—Five ambulnaces for use in connection with the Emergency Relief Organization in the event of an attack on the City of New York by enemy aircraft, submarines, or disaster of any kind, have been donated to the Police Department and have been placed in Police Department garages in various parts of the city. The donors of these ambulances are the Calvary Episcopal Church, Church of the Ascension, Knights of Columbus, Friars' Club, and the Fifth Masonic Division. The name of the donor appears on each ambulance.

Navy Has Plenty of Medical Supplies.—Secretary Daniels has made an official denial of the rumors that the United States Navy is short of medical and surgical supplies. He states that there is an abundance of all medical supplies on all ships, and that the medical supply depot at Brooklyn is packed with enough supplies to last for months to come. Private individuals should not attempt to supply ships unless requested to do so.

Girls Killed in Hospital Air Raid.—In a recent German air raid on the Belgians more than fifty girls were killed by air bombs launched upon an ambulance park at La Panne, behind the Yser front. The girls were engaged in making bandages and repairing linen for the wounded.

Shore Drives for Sick Soldiers.—A new line of war service work has been initiated by the Brooklyn branch of the National League for Women's Service. This organization has established a convalescent home for soldiers and sailors on the Shore Road at Eighty-ninth Street, Brooklyn, to which are brought convalescents from various military and naval hospitals for a day's outing. The home has received a letter from Secretary Daniels expressing appreciation of the work.

Sisters of Charity Join Red Cross.—American Sisters of Charity, for the first time since the beginning of the war, have enlisted as Red Cross nurses. St. Vincent's Hospital of Birmingham, Ala., has organized the Loyola Unit, known as Base Hospital 102, consisting of ten sisters, including a dietician, laboratory assistant, secretary, and 90 Red Cross nurses. The sisters wear the habit of their order but in all other respects submit to the rules of the Red Cross.

Army Doctor Sentenced for Neglect of Duty.—Charged with having contributed to and accelerated the death of a soldier through gross neglect of duty, in that a careless diagnosis was made with the result that proper medical relief was not furnished, an officer of the Medical Reserve Corps, stationed at Camp Dix, has been sentenced to be dismissed from the Army and to serve one year imprisonment at hard labor.

Influenza Among German Soldiers.—According to a cablegram to the Associated Press, it has been learned, through captured documents and statemade by German prisoners, that the Germans are suffering extensively in numerous zones from the influenza which is running through Europe. The affection is said to strike down the men so quickly that they drop in their tracks while on duty. They have high fever for two or three days and are usually laid up in the hospital for six days.

Roumania Honors American Physician.—Dr. J. Breckinridge Bayne of Washington, D. C., who recently arrived in Berne, Switzerland, after having been held a prisoner for a time by the Germans, had brought with him a decoration bestowed upon him by King Ferdinand of Roumania for his efficient work in fighting typhus in that country.

Dental Surgeon Killed.—Dr. Weeden E. Osborne, a Dental Surgeon of the Navy during the advance in Bouresches, France, on June 6, at great risk to his life, performed heroic deeds in aiding the wounded. He was struck by a shell while carrying an officer to a place of safety. He has been cited posthumously by Gen. Pershing for a Distinguished Service Cross.

American Wounded in London — American wounded are arriving in London in considerable numbers from the sections in France where Americans are brigaded with the British. As soon as they reach the hospital their arrival is reported to the American Army Medical Service and to the American Red Cross. It is expected that as soon as the Americans take over the two hospitals which the Red Cross recently announced were to be used exclusively for Americans most of these men will be transferred from the hospitals where they are to a hospital which has a staff of American doctors and nurses.

Rest Houses for Sick Soldiers.—The American Red Cross has opened its rest house in connection with the Walter Reed Army Hospital in Washington. This is one of forty-four such homes which the Red Cross has built or is building in connection with every camp hospital. These rest houses are being provided in connection with the army hospitals at the request of Surgeon-General Gorgas. They will also be built at all important naval hospitals. For the erection of the fifty or sixty that will be needed the Red Cross has set aside $512,000. In addition to that at the Walter Reed Hospital, houses are now open at Camp Upton, L. I., Camp Devens, Mass., General Hospital No. 1, New York, and Camp Dix, N. J. Thirty-nine similar houses are being rushed to completion at other camp hospitals.

Knights of Columbus Extend Work. — The Knights of Columbus now have 150 buildings in France and are rapidly increasing the number as the American Army expands. The organization announces that it has 350 secretaries in France and is now appealing for 2,000 more to man the 100 additional buildings now under construction. The organization now plans to expend $50,000,000 in its work for the coming year.

Another German Victory.—German aviators bombed the American Red Cross Hospital at Jouy, France, on July 15, killing two and wounding nine, among the latter a nurse. Miss Jane Jeffrey.

New York, July 20, 1918.

ONE HUNDRED CASES OF ICTEROHEMORRHAGIC SPIROCHETOSIS.

NOLF and Ficket report this series in the *Archives Médicales Belges* for April. The material was seen during 1917. In regard to epidemiology the order of incidence is naturally of significance. But four cases were seen during the month ending June 20, and twenty-six the following month, with a drop to eighteen in the third, and a rise to twenty-seven in the fourth month. The monthly figures then fell respectively to eleven, ten, and four. There seems from this to be a relationship, then, between summer weather and disease incidence. The ten-day figures show two maxima at June 20-30 and September 10-20. Each of these periods was preceded by very hot weather. At the same time animal experiment makes it very probable that the sewer and trench rats act as reservoirs for the spirochete, while the intermediary, believed to be some stinging insect, has not yet been determined.

In practically all the material the patients entered the hospital on the fourth or fifth day of the disease—hence we have no first-hand knowledge of the early symptoms. From the testimony of the patients it is evident that the inception is sudden, with headache and prostration. Myalgias are complained of in the posterior aspect of the thighs, the calves, flanks, loins, and nuchal region. The muscles are extremely sensitive to pressure. There is moderate fever, while the pulse seldom exceeds 100. The blood pressure is very low, with 120 as the maximum. Prostration is marked, and this, with induced muscle pains, makes even turning in bed a hardship. An experienced practitioner will make the diagnosis from this behavior alone. The conjunctiva and ciliary body are injected and the subject complains of pains in the eyeballs whenever he looks upward or sidewise. A bronchitis is present with an harassing cough. The sputum, which is scanty, may be streaked with blood or at times there is hemoptysis without physical signs of bronchitis. The presence of blood in the sputum is the earliest hemorrhagic symptom as it is the most constant. Only when the subject is hemophilic do we find purpuric and scorbutic types of hemorrhage.

Tests of coagulation time show that this is somewhat delayed, varying directly with the degree of the hemorrhagic tendency. At the outset the stools are of normal color and consistence. Diarrhea was present in but 4 per cent. The liver is but slightly enlarged. There are anorexia and vomiting, the former constantly and the latter commonly present. Quite a degree of meteorism is frequent. There are almost always albumin and urobilin in the urine in the first few days. There is habitually a leucocytosis with polynucleosis.

The symptoms grow steadily worse from the first to the sixth day, at which period the conjunctiva is seen to be icteric. On the following day icterus becomes generalized. Bile is now present in the urine. The stools may or may not become blanched, depending on the degree of icterus. The latter appears to represent a stage of acme of the disease, and around the ninth or tenth day all of the symptoms begin to improve notably. For some five days more the patient, although without fever, is very weak, though no longer prostrated. The cycle of the icterus is about eight days.

Defervescence is followed by critical polyuria, which persists for perhaps a week, the patient voiding from three to five quarts daily for four days. But all is not over with these crises, for the malady is essentially remittent; somewhere between the fifteenth and twentieth days the temperature rises and stays up for a week, reaching a higher mark at times than the initial fever. There is, however, no accompanying general reaction of severe subjective symptoms. The second defervescence occurs on the twentieth to the twenty-fifth day, but the patient may not regain his normal status until the end of about six weeks, and this takes no account of residual weakness, anemia, vertigo, shedding of hair, etc.

The above description fits the typical case of moderate severity in which recovery occurs. In certain cases the subjective manifestations or the prostration are especially in evidence, but the authors do not mention any fatal cases such as have been described especially by the Japanese.

THE ACRIDINE DYES IN THE TREATMENT OF SEPTIC WOUNDS.

WITHIN the past year or so the bactericidal properties of acridine dyes have been highly extolled, and attention has been drawn to the fact that contrary to most antiseptics their action is enhanced in the presence of serum. In *American Medicine* for May, 1918, are two notable papers on this subject, one by Dr. R. Tanner Hewlett of London and the other by Dr. Douglas H. Stewart of New York. Hewlett deprecates the excessive praise that has been showered upon flavine recently by certain observers and he points out some of its drawbacks, especially its slow action as a bactericide. Hewlett quotes the conclusion of Drummond and McNee as regards the practical treatment of wounds with flavine, to the effect

that flavine appears to have many advantages in the treatment of recent war wounds, such as (*a*) absence of all toxicity, (*b*) prevention of suppuration and spreading sepsis, (*c*) the primary dressing need not be changed for two or three days, (*d*) the wounds are not inflamed or painful. But flavine cannot be classed as a success in the treatment of the later stages of war wounds. The wounds tend to assume a stagnant condition during which the processes of repair are almost in abeyance. After a few days when the dangers of gas gangrene and of spreading sepsis have, to a large extent, passed off, flavine should be stopped and another treatment adopted. In the majority of cases, wounds are not rendered bacteriologically sterile even by the prolonged use of flavine.

Hewlett, like so many others, who have had experience in the treatment of war wounds, has been forced to the view that "good surgery" is the essential for success. That is, thorough cleansing and complete removal of all foreign bodies and material, and free drainage. He questions, moreover, after this has been done, whether hypochlorite solutions are better than some other antiseptics and would like to see some of the high coefficient phenoloid disinfectants, which have a comparatively low toxicity, and some formalin containing disinfectant applied by the Carrel-Dakin method and the results compared with those from Dakin's solution.

Dr. Stewart points out that on account of the innocuousness of brilliant green and especially acriflavine, when applied to damaged animal tissues, contact with these dyes does not incommode parasites. In some instances, when conditions were favorable, maggots were observed by Stewart to crawl over the green stains without being discolored or appearing to suffer the slightest inconvenience. Nevertheless Stewart states that the good results that have followed the application of the green solutions are all that have been claimed for them, save for one disadvantage. Stewart sums up the drawbacks of the greens when dissolved by stating that they are excellent germicides, but not parasiticides, and when gauze bandages are soaked with such solutions and placed upon wounds these adhere.

It would seem that the value of the acridine dyes from the antiseptic standpoint have not been, by any means, accurately assessed as yet. It is likely as Hewlett suggests, from a consideration of the results gained from experiments and practice by others that the use of flavine in the treatment of wounds may be as a primary agent extending over a few days, other antiseptics being then substituted for it.

FRACTURES OF THE TIBIA FOLLOWING THE REMOVAL OF A BONE GRAFT.

Apparently it has not been sufficiently realized that a tibia from which a bone graft has been removed needs protecting splints for a rather extended period, if one would avoid the danger of fracture; for although such fractures have occasionally been reported, it is evident that the fact that the weight-bearing property of the maimed tibia and its power of resistance to lateral strain have been markedly interfered with, and are not regained for many weeks, needs to be emphasized.

This is well shown by the experience of John A. Brooke, *American Journal of Orthopedic Surgery*, June, 1918, who reports three cases in which fracture occurred in patients who were allowed to walk without support to the weakened tibia, at the end of four or five weeks. In his first case, a man of 24 was allowed to walk without support at the beginning of the fifth week. About a week later, upon rising from a chair, he made a misstep and slipped on the floor. There was immediate severe pain in the leg, and radiography showed a fracture beginning at the upper and inner angle of the cleft from which the graft had been removed, and extending obliquely upward nearly through the shaft. The second patient was a physician, 38 years of age, who was allowed to walk without support at the end of four weeks. A few days later, while going downstairs, he slipped, and brought sudden weight on the leg from which the graft had been removed. The *x*-ray in this case showed a fracture beginning at the lower angle of the space from which the graft was removed and extending obliquely downward well across the shaft. The third case, that of a man 47 years of age, occurred in the service of Dr. James K. Young. This patient made a misstep while walking in the yard, during the fifth week after operation, turned his ankle, and fell. The *x*-ray showed fracture of the tibia beginning at the upper angle of the area from which the graft was removed, and extending obliquely across the tibia. In all these cases the graft was removed by motor saw, hence it is reasonable to suppose that the minimum of trauma was inflicted.

Very little evidence of regeneration at the site of removal of the graft is shown in a radiograph which accompanies one of the reports, and it is evident that a tibia from whose crest a graft is taken should be supported for considerably more than the four or five weeks allowed in these cases. Adequate prophylaxis is so simple and easy, and the results from its neglect may be so disastrous, that accidents of this sort seem particularly regrettable as well as unnecessary.

ETIOLOGY OF DYSENTERY.

Aldo Castellani, the distinguished authority on tropical medicine, now connected with the Italian naval medical service, contributes an article on this subject in the *Annali de medicina navale e coloniale* for January-February. The distinction between diarrhea and dysentery was known to Hippocrates and equally to Charaka and Susruta. In Sanskrit dysentery was denoted by a word meaning bloody-mucous-diarrhea, of which an acute and a chronic form were recognized. The conception of these troubles has come down to us

undisturbed. The author recognizes dysentery proper and pseudodysentery or dysenteriform syndromes. The former is divided according to the exciting cause into four groups, bacterial, amebic, ciliate, and spirochetic, while dysenteric syndromes are due to malarial parasites, Leishmania, various worms, and certain arthropoda, and finally to mineral poisons.

Passing by the well known amebic and bacterial types, we note that of the various ciliate parasites in the human intestine, only one—*Balantidium coli*, is known positively to cause a true dysentery, although seven other species may possibly set up the disease. Spirochetes have been accused on rather doubtful authority by a few writers. The flagellates, such as Trichomonas and Lamblia—genera accused by Escomel and others as causing dysentery—are exculpated by the present writer.

In the diagnosis of dysentery it is necessary to exclude the pseudodysenteries. If a malarial subject develops dysentery it is most often the case that a true double infection has occurred, but exceptionally the plasmodium is able to set up a dysenteriform syndrome. In the latter case the symptoms subside promptly under quinine. The same may be said of kala-azar and dysentery, when antimony has a specific control of the bowel syndrome. Under pseudodysentery from worms the author relates a case due to one of the schistosomata. If there is a suspicion of mercurial poisoning in a case with dysenteric stools, the urinary examination at once clears up the diagnosis.

"Spanish Influenza."

During the past six weeks or so, much has been said in dispatches from Europe of a mysterious malady which appeared first in Spain and spread thence to other parts of the Continent. The German army is said to have suffered severely from its visitation, and it was even conjectured that the delay in the long-expected drive was due to its prevalence among the troops of the Crown Prince. At first, the disease was unrecognized, and the public press and even some medical papers gravely discussed its symptoms, which, when analyzed, were seen to be those of ordinary influenza of rather mild type. As a matter of fact, it is nothing more than a widespread epidemic, almost a pandemic, of influenza. We learn from *El Siglo Medico* that it first attracted attention in Madrid during the celebration of the religious festivals in May, when the town was packed with visitors. The mysterious part of it was its sudden outbreak in that one locality, but inquiry showed that it had prevailed more or less for some time in other cities of Spain. A little earlier, Chauffard, in Paris, called attention, at a meeting of the Société médicale des hôpitaux, to the epidemic incidence of a febrile affection recalling in its general features the influenza of 1889. Influenza prevailed in this country also to an unusual extent in the early spring. On March 30 it was stated in the news columns of the Medical Record that the Board of Health of this city had issued a warning regarding exposure to grippal infection, it being said that not since 1889-90 had the disease cut so heavily into the working forces of large employers of labor, both in offices and shops. A week before that one hundred cases were reported in Sing Sing prison, and two weeks later it was reported to be crippling the work of the Ford Motor Company in Detroit, 2,000 of the employees having been attacked within a period of ten days. And so the mysterious "Spanish influenza," which the Germans call "Flanders grip," is merely epidemic influenza, which appears to have started on its travels from America, going eastward in a direction opposite to that usually taken by the great pandemics.

Saliva as a Vulnerary.

The fact that a dog heals its wounds aseptically by constantly licking them has been explained by the formation of antibodies generated by the swallowed disease germs or toxins; the veterinaries indeed give the wound discharges to wounded animals by the mouth after and even in the absence of sterilization. The only other explanation of this fact, if it be a fact, is the bactericidal and vulnerary powers of the saliva. In the *Journal de Médecine de Bordeaux* for May, 1918, Dr. Grevin deplores the fact that he has neither laboratory nor library to investigate this subject, but he believes that a study of the ingredients of saliva could throw much light on the preparation of an antiseptic solution to be used as a wound dressing. The belief in the vulnerary properties of saliva *per se*, aside from any possibility of conferring immunity by swallowing, is old and the simple admonition to spit on a recent insect bite as the utmost that is necessary is encountered at times among practical members of the laity who come much in contact with these injuries. Such advice used to be given by a veteran insect exterminator whose empirical knowledge must have stood for something.

News of the Week.

German Hospitals Change Name.—The German Hospital in Manhattan has changed its name to the Lenox Hill Hospital. The German Hospital in Brooklyn will take the name of the Wyckoff Heights Hospital.

Infants Examined in Straus Milk Stations.—Nathan Straus has given instruction to Dr. Michael Schuman, physician in charge of the Straus milk activities and to his assistants to begin the examination of children who may be brought to the depots with a view to advising the mothers of these children as to the health needs of these infants. The work is part of the plan of the Federal Children's Bureau to save 4,700 children's lives in New York City.

Cholera in Russia.—According to a report coming through London, hundreds of persons in Petrograd are daily fallings victims to cholera. Authorities state that it is impossible to do anything to combat the epidemic owing to the very serious shortage of food, it being impossible to furnish even a quarter of a pound of bread daily. The Russian Council of Commissioners had made a most urgent appeal to the councils in the corn

provinces and to the railways to send food to Petrograd as rapidly as possible.

To Fight Yellow Fever in Ecuador.—An American sanitary commission, including four doctors and six nurses, headed by Dr. A. K. Kendall, has arrived in Guayaquil for the purpose of cooperating in the endeavor to wipe out yellow fever in that locality. The commission was sent by the Rockefeller Foundation.

Students in Maternity Hospitals.—It is reported that many mothers are being attended in childbirth by medical students at the Chicago Lying-In Hospital as a result of the shortage of regular surgeons. Publicity has been given to this innovation by an investigation of the State to determine whether the procedure is legal.

Call for Classification of Convicts.—The New York State Commission on Prisons, of which Dr. Walter B. James is chairman, met in the New York Academy of Medicine on July 12, to discuss problems in connection with mentally defective criminals. Resolutions were adopted calling for a classification of prisoners on a mental basis. The resolutions set forth that if a record were kept of each inmate's brain capacity prison authorities would be able to follow better methods in dealing with convicts.

Medical Jurisprudence Society is Defunct.—The majority of the members of the American Association of Medical Jurisprudence have filed an application in the Supreme Court for the dissolution of the corporation. The petition shows that the membership has decreased from 200 to 23, and that there is a general lack of interest in the organization. An order has been signed directing all persons interested to show cause, on July 30, why the corporation should not be dissolved.

Floating Hospital Begins Season.—The Floating Hospital of St. John's Guild of New York made its first trip for the present season on July 12. The floating hospital makes trips between various points in New York and Brooklyn to the hospital of the Guild at New Dorp, S. I. This is the fifty-second year that the guild has given this service to sick children of the poor.

Rally for New York Infirmary.—The auxiliary committee of the New York Infirmary for Women and Children, New York, recently held a patriotic rally at the Hotel McAlpin for the purpose of discussing ways and means of raising the $200,000 needed to continue the work of this hospital. This is the second rally held within a couple of weeks for this object. Dr. Angenette Parry is chairman of the committee.

Act to Incorporate Medical Society.—The Senate, on June 30, passed an act to incorporate the Medical Society of the District of Columbia. This society was originally chartered by Congress in February, 1819, and the charter having fallen into disuse was revived in 1883. By the enactment, in 1896, of the medical practice act for the District of Columbia, a large part of the charter which formerly had licensed practitioners of medicine was repealed. The society is planning to acquire a building of its own in which to transact its business and for this reason the revival of the charter has been requested.

Feud in Birth Control League.—An official announcement from the headquarters of the Birth Control League in New York City states that this organization has severed its connections with Mrs. Margaret Sanger, who served thirty days in the Queens County Jail for the dissemination of information about birth control. The reason given for this action is that a disagreement has arisen between Dr. Frederick A. Blossom, one of the founders of the league and Mrs. Sanger as to the management of the league, and the league is supporting Dr. Blossom.

Amend City Ordinance to Help Hospitals.—The New York Civil Service Commission announces that a serious situation arising in the city hospitals due to the ordinance passed in 1913 requiring that all city employees be citizens of the United States has been met by an amendment of the ordinance by the Board of Aldermen, permitting the employment in institutions for the sick and infirm, and in dispensaries, clinics, and laboratories, of aliens of neutral or allied countries. Until this ordinance was amended the city faced the prospect of closing many of the hospitals because many employees in these institutions had been drafted or had enlisted and a large number were enemy aliens whose services were dispensed with as soon as war was declared.

Blind to Use Braille Type.—The American Association for the Blind, after ten years' discussion, has adopted the revised Braille type as best adapted for the use of blind readers. The other forms of type for the blind will be gradually discarded in future publications.

Dr. Friedrich August Richard Strensch, a practising physician of this city, a graduate of the Baltimore Medical College in 1898, has been arrested on a presidential warrant as a dangerous enemy alien.

Dr. Maud Kinnaman, formerly of Washington, N. J., has been made head of the new medical college at Vellore, India.

Dr. George T. O'Donnell has been appointed health officer for the Connecticut Valley district to replace Dr. W. S. Hitchcock, who has been made director of the division of communicable diseases.

The Des Moines Valley Medical Association, at its annual convention in Des Moines, Ia., on June 27, elected the following officers: *President*, Dr. S. K. Davis of Libertyville; *First Vice-President*, Dr. M. F. Moore of Ottumwa; *Second Vice-President*, Dr. T. P. Jackson of Albia.

English Birth Rate Falling.—Sir Bernard Millet, the Register General, in a recent lecture, stated that in England and Wales the births registered in 1913 were 881,890; in 1915 they fell to 814,614, in 1916 there was a still further fall to 780,820; in 1917 they fell to 668,346, a decline from the 1913 figures of 24 per cent. Up to the present England and Wales are said to have lost in potential lives 650,000 on the standard of 1913. It is believed that without exaggeration it may be said that the war has thus far cost belligerent countries of Europe not less than 12,500,000 potential lives. At the present time every day of war is said to mean a loss of 7,000 potential lives among the Allies and the Central Powers. Race

suicide on a colossal scale has been the outstanding result of German militarism.

British Women Want Schools for Defectives.—A special subcommittee of the Joint Parliamentary Advisory Council, composed of women social workers and members of Parliament, has just issued a report upon existing permissive educational provision made for defective children. The report calls attention to the need of making the acts of Parliament dealing with these children compulsory and not permissive. The report states that there are in the country to-day between 37,000 and 40,000 children, who are cripples or otherwise defective, the greater number of whom are being deprived of educational advantages. There are in London thirty-seven schools for the physcially defective with an attendance of 3,700 children. There are fifteen districts in England and Wales that possess these schools. The special committee is asking for compulsory powers under the education bill and for the establishment of special residential schools for defective children.

Hospital Cornerstone Laid.—The cornerstone of the new People's Hospital was laid with appropriate ceremonies on the afternoon of June 30. The building is located at 203 Second Avenue, New York City, and will be a ten-story structure with all modern facilities.

Obituary Notes.—Dr. William Hunt Hall, a graduate of the New York University Medical School, in 1858, died at his home in New York, on July 8, aged 85 years. He was surgeon in charge of a Confederate base hospital near Petersburg during the Civil War.

Dr. N. Curtice Holt of New York, a graduate of Bellevue Hospital Medical College, in 1896, died suddenly in Webster, N. Y., on July 8, aged 65 years. He was a brother of Dr. L. Emmett Holt of New York.

Dr. Aaron A. Mendel, a graduate of a medical college in Roumania, in 1896, died at his home in New York City on July 12.

Correspondence.

PART-TIME NURSING SERVICE.

To the Editor of the Medical Record:

Sir:—The Red Cross demands the enrollment of 25,000 nurses for the army and navy, for public health work connected with the encampments, and for reconstruction work at home and abroad. This will greatly deplete the number of trained nurses available for private duty. The Red Cross exempts those nurses who are indispensable to the Department of Health and to the visiting nurse services, and a chevron indicating this recognition of their patriotic service at home will be issued to these nurses.

The needs of the country require a sacrifice on the part of the nurse-employing public and physicians to engage a private-duty nurse only when absolutely necessary. To meet the need of the public the Visiting Nurse Service of New York, administered by the Henry Street Settlement, is ready to answer calls from all classes of society where the full time of a nurse is not essential. The staff consists of about 150 nurses, all graduates of recognized hospital training schools, and especially trained in the technique required in visiting nursing. They are qualified to carry out physicians' orders for special treatments as well as general care. Every precaution is taken to safeguard the patients, and a special group of the staff is assigned to the care of patients suffering from contagious diseases and another special group takes care of maternity cases only. The nurses caring for general medical and surgical cases also observe a very careful technique as they pass from case to case.

This letter is addressed to those of your readers who may not be aware that the Visiting Nurse Service is meant for people of all classes. It is sincerely hoped that they, and their patients, who up to this time have used the full time of the nurse, will recognize the obligation to free such nurses whenever possible for war service.

Lillian D. Wald, R.N.
L. Emmett Holt, M.D.

New York.

THE STATE NARCOTIC DRUG LAW.

To the Editor of the Medical Record:

Sir:—The representatives of the Medical Society of this city who failed before Governor Whitman in their opposition to the law for a State commissioner of drugs will restate the objections which they placed before him in regard to this measure before the informal convention of the Republican party of this State at the Saratoga convention this week.

The result of drug laws in this State up to the present time has been to demoralize the practice of medicine so far as relates to the prescribing of opium. They have caused untold suffering and death to those having to use this drug, owing to drug laws harshly enforced by ignorant administrators. They have developed a new criminal industry more profitable and less risky than robbery, crimes of violence, or ballot box stuffing, from all of which vocations many of its members have been recruited. This class the police are powerless to suppress, for what reason is not known. The law for a commissioner of drugs has advantages of political patronage. It penalizes physician and patient and lets the drug peddler alone. Many physicians today are afraid to prescribe morphine in sufficient doses to patients dying of cancer. Of course, they are ignorant of their right to do so, as they have been terrorized by drug laws. Such a patient, using morphine in quantities, cannot be admitted to a public institution of mercy without having to be committed there like an incompetent, an inebriate, or a criminal.

John P. Davin, M.D.

New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MEDICAL SIDE OF RECRUITING—MURDER OF PROFESSOR POZZI—SMALLPOX IN LONDON—HOSPITAL SUNDAY FUND—CARDIAC AFFECTIONS IN THE SOLDIER.

London, June 19, 1918.

Sir Auckland Geddes, the Minister of National Service, has had rather a difficult task of late in the House of Commons to explain to a body of lay-

men the medical principles upon which the grading of recruits are founded. In stating that there had been no change in the standards of medical fitness required for classification in Grades 1 and 2 since the Ministry of National Service took over recruiting from the War Office, he pointed out that Grade 1 meant men who presented "a normal standard of health and strength and are capable of enduring the physical exertion suitable to their age," quoting the words from the Recruiting Code, and added that in the medical grading of recruits current statistics covering a large number of examinations showed no increase in the proportion of men placed in Grades 1 and 2 by his Ministry. Grade 2 was generally equivalent to Category B1 and Category C1 in the old military classification, and included men passed for garrison service at home and abroad. Sir Auckland Geddes stated further that the number of complaints by the recruits as to the methods or results of examination by the civilian boards was not large, and that most of the cases, when inquired into, were capable of satisfactory explanation. But while for medical reasons the simple classification into three grades, or at any rate into a small number of divisions has every merit, it is clear both from Parliamentary questions and communications to the lay press that the tribunals are now seeking a more detailed grading of the men in order to facilitate their work in allotting the men to military or civil positions. Such grading complicated with questions concerning any man's particular fitness for military or civil work is hardly the duty of civilian medical boards, who have to decide simply to which of certain grades of physical fitness a man belongs. When it became fairly certain that the military age would be raised by a new Military Service Act, the matter of grading was carefully considered by the Ministry of National Service, the lines of possible procedure being clearly two: (1) To institute a new system of grading for the men of the older years; (2) to continue the system of grading already in use and apply it to the older men. The view taken by the Medical Department of the Ministry was that, to introduce any system of grading with a lower limit at such an advanced age as 43, though the idea would surely appeal to the lay mind, would have no firm foundation either on medical reasons or on reasons of efficiency for military or civilian work, while the innovation would interfere with the system of grading already in operation. The Medical Department of the Ministry consulted high medical authorities and received the opinion clearly and firmly expressed, that it would not be possible to establish different systems of grading for men of different ages. As a result the existing orders to medical boards place upon these boards an entirely new responsibility for this country, though it is one with which the countries where military conscription holds are quite familiar. All the foreign military powers have an older army which is developed alongside their younger army. From these older men military work of a certain character and up to a certain standard is expected. It is the hard case of this country that similar work is expected of our middle-aged men without the early training.

A real tragedy was enacted in Paris on June 13 when Professor Pozzi, certainly one of the most famous European authorities not only on gynecology but on abdominal surgery was murdered in his consulting room by a lunatic patient, who thereupon committed suicide. Samuel Pozzi, who was seventy-two years of age, though he presented a far younger appearance, was a native of Bergerac, was educated at the neighboring lycées of Bordeaux and Pau, and just fifty years ago went to Paris as a pupil of the great Broca. His gynecological work attracted public attention from the beginning, and at the age of thirty he was appointed to the professorship in the subject founded by the municipality of Paris at the University. A man of wide learning outside professional subjects, no narrow specialist within these subjects, a fair linguist, a prolific writer, and a picturesque personage, Pozzi acquired a world-wide reputation as a scientific ambassador. To him the French Government entrusted scientific missions on various occasions to all the European powers and to the United States, and he became a general interpreter at international congresses of the aims and accomplishments of different schools of medical thought. He acted as Secretary-General of the French Congress of Surgery, was President of the Surgical Society of Paris, and Vice-President of the International Congress of Gynecology held in that city in 1900. He was a Senator, a member of the Academy of Medicine, and shared with (among others) W. W. Keen, G. W. Crile, Harvey Cushing, W. J. Mayo, and J. B. Murphy the rare distinction of the honorary Fellowship of the Royal College of Surgeons of England. Pozzi is not the first well-known doctor to be murdered by a patient, while attempts on the lives of doctors by disappointed invalids have been chronicled in every country. In England the threatened doctor is usually the alienist upon whose certificate detention in a lunatic asylum has followed, but though the threats are quite common the attempts are rare.

The epidemic of smallpox in London, to which attention was drawn in your issue of May 4 in one of these letters, has not quite died down. Only 3 cases were notified during the month of May, and only 3 cases remained at the beginning of June in the Fever Hospitals of the Metropolitan Asylums Board, as against 13 at the beginning of May, and 30 at the beginning of April.

June 23 will be Hospital Sunday, and on that day collections will be taken up for the Metropolitan Hospital Sunday Fund in many places of worship of all denominations within the metropolitan area, the money being devoted to the voluntary medical charitites of London and the immediate environment. King Edward's Hospital Fund for London, though a much more modern institution, is larger in capital and in scope than the Metropolitan Hospital Sunday Fund, and it was at one time feared that the public might consider that subscription to the Royal foundation removed any lien upon them to subscribe to the older charity. The apprehension has been found incorrect. The Metropolitan Hospital Sunday Fund receives every year from the charity of worshippers a sum of between £40,000 and £60,000, and this is about the same sum that used to be received before the late King

Edward VII (then Prince of Wales) started the noble movement with which his name will ever be associated. There is again this year, as there has been for the last three or four years, a very pertinent reason why the public should give ungrudingly to the support of the voluntary hospitals of the metropolis, and that reason is that so many beds in these hospitals, general and special, have been placed at the disposal of the War Office on extremely favorable money terms for the use of the sick and wounded of the war. For these patients the War Office makes a capitation payment, but the prices of food, heating, lighting, and medical material have all increased so enormously that the capitation grant, though it has recently been increased, only slightly lightens the financial burden of the hospital authorities. The old capitation grant was 4s. per diem, but during this year the figure has been raised to 4s. 9d., and even at this rate a considerable debt is due to the hospitals. A recent report on the subject issued by the War Office and signed by Dr. E. N. Burnett and Mr. R. Orde, has been distributed by the British Hospitals Association, and throws interesting light on the manner in which civilian hospitals have assisted in the care of sick and wounded soldiers. It is clear that the additional burden placed by these patients upon voluntary hospitals during the war has been manfully met, but it is clear also that some of the hospitals are run in a vastly less economical manner than others. The cost to different hospitals for food, for fuel, and for laundry varies extraordinarily and in a way that cannot be accounted for either by any special character of the institution, by locality, or by the class of patients received. The range of prices for surgical dressings, the extent to which salaries have to be paid, the daily cost of surgery and dispensary, including the consumpton of surgical dressings; all these things apparently are governed by no general law, some institutions being quite extravagant, and others remarkably parsimonious. The War Office has no doubt distributed the report to show that it is not the Government that is parsimonious, but the charities which are profligate in the use of public money. This is not the general conclusion to be derived from a study of the evidence, but none the less the report forms a very pertinent reminder to hospital managements that good and worthy objects cannot be treated as a complete excuse for extravagance or for perfunctory supervision. The reminder is needed in a good many places.

A memorandum forming one of the Special Report Series of the Medical Research Committee, and supplementary to previous reports, has been issued by the Committee, dealing with the position of soldiers who have been sent back from active service as cases either of disordered action of the heart (D. A. H.) or valvular disease of the heart (V. D. H.) The latest memorandum has been written by Dr. Thomas Lewis, a prominent member of the research staff of the Committee, and assistant physician to University College Hospital, London, and it forms a detailed comparison of the plight of patients falling under one or other of the categories. The syndrome of effort, as displayed by soldiers returned to hospital, is found mostly among those offering no physical sign of structural disease, though it is also displayed by those in whom clear signs of mitral or aortic regurgitation are present. Of those who displayed symptoms on active service the non-valvular cases show a higher percentage, but this is because many valvular cases have been returned to hospital in the course of training. But naturally those in whom the valvular lesions have escaped detection are those in whom those lesions are the least serious. When disordered action of the heart is associated with signs of structural disease the condition has generally occurred among men who have been recruited to the army from sedentary and light classes of work, but it must be remembered that recruits are taken generally from more arduous employments. A high percentage of cases occurs in the sedentary and light classes, and is largely due to the unfitness of the men before they join, though faulty or too rapid training plays a part. But even among the soldiers invalided for grave heart disease the larger percentage occurs among those employed formerly in light work. Among the non-valvular cases, previous infections of various kinds play a great part, promoting a liability to cardiac failure in some 50 or 60 per cent. of cases where the effort syndrome is uncombined with clear signs of structural disease. This point has already been made in a previous memorandum of the Medical Research Committee, and Dr. Lewis now finds that the incidence as far as past histories of infectious disease are concerned is not dissimilar, whether in valvular or non-valvular cases, though in valvular disease the onset, when marked by any special event, dates most frequently from rheumatic fever. Gas poisoning and shell shock both have an influence analogous to that of infection. The sobriety among the men of the new British armies both before and after joining the service makes the question of the consumption of alcohol rather academic in the discussion of the etiology and development of cardiac disease.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

GOOD HEALTH CONDITIONS IN THE AMERICAN CAMPS —AN AMERICAN BASE HOSPITAL—WORK FOR CHILDREN AT TOUL—PROVIDING FOR THE TUBERCULOUS AT PARIS—AMERICAN FUND FOR FRENCH WOUNDED.

PARIS, May 28, 1918.

MOTHERS of America have no cause to fear for the welfare and health of their sons in France. Sanitary conditions are of the best in all the camps, and there is very little illness. Though the winter has been treacherous, and the men had to commence camp life at a bad time of the year, they have not suffered in the least, as particular attention has been paid to the supply of warm clothing and all of the buildings at the various camps are well heated. The field hospitals are in fine running order, and the men are as well taken care of as in any of the first-class hospitals of a city. It is most gratifying to see these boys who are so far away from home and mother being taken care of by good American nurses, and to find them so happy and contented with their surroundings.

In visiting the American camps, I looked in at one of the base hospitals. It was the first base hospital to be established for the American troops, and came over with the first contingent last June. The staff is composed of the Johns Hopkins Unit from Baltimore, with Miss Bessie Baker as the general directress and chief of sixty-two nurses, with a major as ranking officer. At present about 800 patients can be cared for, and new buildings are being constructed to bring up the capacity to 5,000. The barracks are strongly built, with perfectly equipped operating rooms, and a most efficient medical staff. The hospital is pretty well filled up for the moment with both surgical and medical cases. A number of the wounded have come from the trenches, but the majority of the patients have received their wounds accidentally in the camps or have had colds or appendicitis, but whatever their troubles are they are all as happy as possible under the circumstances. At first, there were more medical cases than surgical, but now there are about as many surgical cases. Although one hears a great deal about the soldiers having colds, and not being able to stand the French climate, there have been very few cases of pneumonia. Indeed, there has been much more pneumonia in the training camps in America than in France.

The hospital has comfortable quarters for the nurses, with nice, bright living rooms and dining rooms, and the food is excellent and plentiful. Entertainments are given for the nurses once a week, and they seem contented and interested in their work. Both the Y. M. C. A. and the Y. W. C. A. have had a share in making the hospital comfortable. There is a Y. M. C. A. hut near, which affords great pleasure to both the staff and the convalescent patients, and the Y. W. C. A. has contributed in many ways, such as giving a piano and gramophone for the recreation room, etc. The hospital was built and occupied by the French before America came into the war, and was turned over to the Americans in July. The staff is entirely American, with the exception of the lingerie staff. It is the French women of the village who do the laundry work and look after the linen.

Toul has become the center of great war activities, particularly in relief work, since the American Red Cross has made it a center of the important work for the children. The accomplishments of the Red Cross in its affiliations with M. Mirman, the prefect of Meurthe-et-Moselle, whose name has become sacred through his wonderful devotion to his people of the department, are truly marvelous. From a meager beginning last July, when M. Mirman telegraphed to the American Fund for the French Wounded that help was needed for 350 children who had suddenly been put in his care, has grown one of the most far-reaching organizations in a matter of real help to the French people that the Red Cross has yet undertaken to nourish. These same 350 children to whom the Red Cross rushed a group of eight emergency workers, to find them herded together in an old barrack that was dirty and unfurnished, and had nothing in the way of sanitary appliances, etc., are now being cared for under the very best conditions. New buildings have been erected and installed with all modern improvements. The hospital, dispensary, and refugee home, where mothers as well as children are cared for, are all well organized and in perfect running order; and what counts for more than anything else, these same little children, now numbering about five hundred, who have been brought from the villages back of the lines, where asphyxiating gas bombs were being dropped, are supremely happy. There are about 35 or 40 American women, nurses, aides, playground instructors, and other trained workers, to look after the children, with Dr. Maynard Ladd in charge of the medical department.

Arrangements are being made to extend the work in many directions under Dr. Ladd's supervision. Toul is to have 700 beds in all, and other bases are being established at Nancy, Pont-à-Mousson, Lunéville, and later there will be a base at Epinal; and sentiment has demanded that Einville be made a base for American work, as it is the village where the first American wounded were brought, and where the monument will be erected. Dr. Ladd has two points in mind in carrying out this work: First, the welfare of the children of France; and secondly, though equally important, the effect that such work will have on the morale of the French army. This may sound somewhat vague, but it is undoubtedly true that the French soldiers can remain in the trenches in a much better frame of mind when they know that their children are being given the best possible care. The workers are looking far into the future, and have in mind conditions after the war; and the fathers in the trenches realize this fact, and, with this vicinity being such a center for all the Allied soldiers, the news of the work is rapidly spreading, and it is bound to have its effect. The bad conditions that were supposed to be found here when the Red Cross came have been greatly overestimated. The French were doing a great work under the direction of M. Mirman, but after three years of war they had reached the point where they were overwhelmed with the burden and had to call for help, so the Red Cross came to the rescue. They came to help and not to teach, and have worked in the closest cooperation with M. Mirman, who is so beloved in this part of the country.

There is no part of France where the French have shown such efficiency in relief work, and there is also no part of France where the need has been so great. The workers have taken children from the villages all along the line where gas bombs were being dropped. In some cases the mothers are with them, but on the whole the work is confined to children alone. It has not been necessary to remove the mothers from the villages, as the adults can wear gas masks; but the little children do not use them successfully, and therefore must be moved to places of safety. The military authorities try to remove all the children under eight years of age. Knowing that their children are in a safe place and are being well cared for, the peasant women are urged to remain and harvest the grain in that district.

Dr. Ladd says that he is increasing the work by opening a new hospital of 200 beds. In fact, the recent raids on Nancy have already opened it. About forty beds are devoted to a maternity ward, which they expected to open next week, but M. Mirman notified them that a bomb had struck a maternity hospital in Nancy, and twelve women would have to be moved immediately, so they rushed

things up to meet that need, and within thirty hours after they received the notice the twelve women were comfortably installed in the hospital, and a baby was born.

The Red Cross can be doing no better work in any place in France than at this base at Toul. The sanitary conditions have been made perfect, and nothing has been left undone that will make the children, who are to be the future of France, strong and ablebodied. It is plain that every department has been looked after in the minutest detail by one who is intensely interested in the work. A special feature is being made of the recreation department, which is under Miss Cleveland of the University of California, where the children are made happy in a dozen different ways and taught to play. The dental department has been greatly developed recently under Dr. Stevens, a woman dentist. Particular attention has been paid to the operating rooms, and every branch of the medical department has been made as perfect as that of any hospital in the cities.

Ground has already been laid out and cleared for a family colony and village community for 1,000 tuberculous refugees just outside of Paris. The plans have just been approved of by the Finance Committee of the American Red Cross. The houses will have three or five rooms. Each will have a porch, and will be of a type which can be dismounted and transported to the devastated districts when the war is over. Dr. William Charles White, chief of the Red Cross Tuberculosis Bureau, and author of the scheme, believes that the Red Cross is thus aiding in solving in France the problems and difficulties presented by the overcrowded cities of America. It is a new opportunity in the history of the world, he declared. The daily entrance from behind the German lines of people useless to Germany, hundreds of homeless folks without any resources for resuming life, has created a problem similar to that of the misfit families which have troubled all big American cities. Many of them are tuberculous. These repatriates without homes create the necessity to provide dwellings in cities where all houses are already overfull. This has opened an unprecedented opportunity to the Red Cross to do what has hitherto been impossible in America, to meet the menace of tuberculosis without breaking up the family group. Fifty acres of meadow and woodland at Malabry, near the American Red Cross Hospital at Plessis-Robinson, has been turned over for the period of the war by the Department of the Seine, and the French Government will pay more than half the cost of the maintenance of the refugee families who will be installed there, so that the total cost will only be about $265,000. All the elements of a thriving French village will be developed. Schools and playgrounds, recreation facilities, a cooperative store, village laundry, community bathhouse, and dispensary, will be established, all in demountable wooden houses capable of transfer to the liberated districts when the military situation makes that possible. Industrial education for those well enough to undertake it, and training in hygiene for all, are also a part of the project. Hitherto, hospital care has meant the breaking up of families. In this case refugee families without tie and connections in the city will be moved bodily to the country village. Dr. White firmly believes that the example of Malabry will be one invaluable contribution to the solution of world-wide problems of urban congestion.

The American Fund for the French Wounded has taken over new duties in its affiliation to the American Red Cross in searching for the American wounded in the French hospitals. Inasmuch as the fund is in communication with 4,000 French hospitals scattered all over France, and having depots in practically every department, it is more capable than any other organization of finding these men who have been picked up seriously wounded and taken to the nearest hospital, and whose whereabouts, for that reason, are often not heard of for a time. The president of the fund says that mothers of America need have no fear of their sons falling into the hands of foreigners who could not understand their language, and therefore be incapable of seeing to all of their little needs, for the A. F. F. W. is everywhere in France, and its one great service is the personal attention that it gives the wounded.

Mrs. Benjamin G. Lathrop, the president of the organization, has recently made a trip to America, where she had a talk with the mothers of fighting men, and she knows what they want. She made addresses in many of the States to the thousands of women who have been supporting the A. F. F. W. and making thousands of garments for the French wounded for the last three years. She gave some idea of the surroundings of the soldiers and the great good that had been rendered through these American gifts. She raised $90,000 without half trying, even though she had gone on another mission altogether, and said that everywhere she went the women were saying "What shall we do? What shall we make? What is most needed?" and that no task was too great for them.

The A. F. F. W., through its president, made it clear to the women of America that its theory as to its method of work was unity of action. "It is not one American boy that is to win the war, as any mother might be inclined to think of her own son," said Mrs. Lathrop, "but it is the big fighting force, and the relief workers are a part of that force just the same as the soldiers. The women at home realize that the unity of force is necessary, and they are all joining the Red Cross because it is our national organization, and working as a body, and it is for the personal touch that they look to the American Fund for the French Wounded. In explaining the conditions in France the work should be divided into three duties: First, the duty of General Pershing; second, the duty of the Red Cross; and third, the duty of the women; and that is the basis on which the American women are working."

1. A Critical Discussion of Sugar in Its Relation to Infant Feeding. Lewis Webb Hill.
2. Dental Diseases in Relation to Diseases of the Nose and Throat. Kurt H. Thoma.

2. Dental Diseases in Relation to Diseases of the Nose and Throat.—Kurt H. Thoma refers to the frequent relation which exists between oral diseases and diseases of the nose and throat. The diagnosis of

dental disease requires careful and painstaking investigation and even though the Roentgen ray has facilitated it, the application of temperature and electrical tests as well as the diagnostic use of local anesthesia are often necessary to ascertain the exact location and nature of the difficulty. Thoma takes up certain typical lesions. He points out that the connection between malocclusion and nasal diseases was noticed by Hippocrates. Bottle feeding and thumb sucking are primary causes of compressed V-shaped arch and protruding maxillary bones; the lack of lateral development prevents expansion of the nasal passages and invites the formation of adenoids, which in turn causes mouth breathing. In such cases nasal respiration must first be established and the jaws given proper orthodontic treatment, which, of course, must be undertaken at an early age. Treatment should be supplemented by a diet which forces the child to masticate and by special exercises of the muscles of the face. Maxillary sinusitis, according to Brophy, in about 75 per cent of cases is due to diseases of the teeth. If large abscesses occur on the upper molars or bicuspids, sinus disease should be considered as a possibility, and, on the other hand, the teeth should be roentgenographed in all cases of maxillary sinusitis. Chronic pharyngitis is frequently associated with pus discharge from sinuses of chronic tooth abscesses, from pus pockets due to ill fitting crowns and bridges, or from pyorrhea alveolaris. Pharyngeal abscesses also are sometimes of dental origin. The fact that pain originating from some dental or oral cause may be referred to distant parts of the face and head is explained by the extensive area of distribution of the trifacial nerve and its frequent communications with other cranial nerves and the sympathetic system. The pain quite often simulates symptoms of sinus disease or is referred to the ear (otalgia dentalis). The tympanic plexus is connected with the second division of the fifth nerve by means of the splenopalatine, or Meckel's ganglion, via the great superficial petrosal nerve, and the third division communicates through the small superficial petrosal nerve and otic ganglion, which also gives a branch to the tensor tympani. The most frequent causes of the condition are pulp-stones (calcareous nodular formations in the tissue of the dental pulp), chemical or thermal irritation of the pulp, pulp infection of chronic character, or abscesses between teeth. The pressure and pain are due to the mechanical force exerted against the obstruction in the effort to come to the surface, or to pressure absorption, affecting a neighboring tooth. The author has been able to collect data to prove that the pain is due not only to the pressure of the occlusal surface of the tooth against the obstructing tissue, but in many cases is caused by the development of the roots in the opposite direction, where they may encroach upon the inferior dental nerve. Thoma reports a number of cases to illustrate his remarks and adds to the value and clarity of his article by the reproduction of some excellent roentgenograms.

3. The Action of Radium on Cataract.—Isaac Levin and Martin Cohen report three cases of different types of cataract which were subjected to radium treatment. In each of these cases improvement of vision was noted within a week of the commencement of treatment, accompanied by an increased visibility of the fundus reflex which could only be due to a decrease in the lenticular opacity. The writers point out that a similar phenomenon has never been reported to have occurred spontaneously or to have been caused by any other agent. It is impossible as yet to say whether this improvement will be permanent or not. The writers, however, have undertaken a broad study of the subject on animals and on clinical material and a complete report will be presented at a future date. A detailed report of the technique employed will also be published later. They state in the present paper that the treatment was based on a case reported in 1911 by Fleming, in which a malignant tumor of the orbit was treated with comparatively small doses of radium. The tumor was diminished to such an extent that the cornea became visible and then a senile cataract was found which was not influenced by the radium nor was the perception of light impaired. They therefore decided that for the treatment of cataract as large quantities of radium should be employed as are now used in the modern treatment of cancer, but with strong filtration so as to avoid doing injury to the normal structures of the eye.

3. The Sin of Treating Symptoms.—H. S. Ward points out the dangers arising from the observation of one leading symptom in diagnosis without considering the patient's condition as a whole. Medicine is no longer the business of an individual; the time has come for team work, and diagnostic units are essential. The clinician must not allow the laboratory and the specialist to make his diagnoses, and the physician who waits for the laboratory to find tubercle bacilli in the sputum waits too long to be of real value to his patient. Many mistakes have been made in diagnosis; inoffensive appendixes have been taken out, normal tubes and ovaries have been sacrificed, and useful gallbladders drained; ptosed viscera have been stitched up or colons removed and healthy stomachs opened only for some painstaking surgeon later to diagnose a diseased kidney. In nervous diseases, the Wassermann test is not sufficient to diagnose syphilis; nor are prolonged rest and polypharmacy enough in chorea; and something more definite than "overwork" must be looked for as the cause of nervous breakdown. Finally, due importance must be attached to oral infection, pyorrhea, and abscessed and carious teeth. The writer reports cases to illustrate the various points raised. In regard to oral infection, he asks, in view of the frequency of diseased teeth in indigents, whether there may not be some connection between this and being "down and out"? As far as the future generations are concerned, the teaching of oral hygiene will remedy matters to some extent. At the present time, however, should the treatment of this condition be radical or conservative? Many deaths have occurred as a result of too radical treatment, and the best results have been obtained by the gradual cleaning up of the pathological condition—by doing a little at each sitting, the patient resting in the meantime. Oral infection will find its proper place in medicine if the whole condition of the patient is considered as a diagnostic problem.

1. The Conditions Under Which the Sterilization of Wounds by Physiological Agency Can Be Obtained.—Colonel Sir Almroth E. Wright, Captain Alexander Fleming, and Captain Leonard Colebrook discuss in some detail their observations on the treatment of bacterial infection of wounds, giving a careful description of the technique adopted. They point out the fallacy of the assumption that the organism is unable to deal with the infecting microbes—in which case there would be bacterial infection from which nobody could recover. They add that in order to ascertain what the body is capable of achieving, we must find out how to bring its powers effectively to bear. They state, (1) Serum from normal blood and normal lymph constitutes for the vast majority of the microbes met with in foul wounds a very unfavorable culture medium; only the streptococcus, the staphylococcus and certain diphtheroid bacilli can grow in unaltered serum, and when a minimal implantation is made the streptococcus alone gives a growth. In other words the microbes of wounds fall into two catagories: serosaprophytes, which grow in corrupted, and serophytes, which grown in uncorrupted blood fluids. Hence, (a) a wound that contains serosaprophytic organisms contains corrupted discharges; (b) if the wound can be flooded with wholesome serum and that serum kept uncorrupted, the infection will be reduced to a purely serophytic, generally to a streptococcic and staphylococcic infection. (2) Trypsinized serum provides an excellent culture medium for practically every species of microbe. (3) Neutralized or partially neutralized serum, such as obtains in every condition of collapse is a medium in which serophytic as well as all the microbes of the gas gangrene class flourish. These latter, however, are not genuine serophytes but serophytes only of acidosed blood fluids, which means that a gas gangrene infection in tissues in cases where the circulation is uninterrupted can be combated by drawing away the acidosed lymph and replacing it by alkaline lymph. (4) The whole blood constitutes a medium of essentially the same quality as the serum, in which only saprophytic microbes will grow. These observers then show by means of experiment that what is essential to the achievement of bactericidal effects is the employment of freshly emigrated leucocytes—which from a clean wound surface are precisely the same as from blood clots—the keeping of these alive and active, and the removal of the excess of serum which would carry the microbes out of reach. The solution of the problem of sterilizing the actual wound surface they believe will be found along these lines. They submit experimental data to show that it is possible to sterilize the superficies of a wound by the agency of antiseptics, provided that the surface has been washed perfectly clean from albuminous substances. Finally they conclude with the following statement of facts proved to be true as against that which has been shown to be erroneous: (1) It has been erroneously inculcated that every wound should be sterilized before closure; and that, therefore. *primory suture* should be avoided and *secondary sutures* undertaken only after a course of antiseptics. There is now no question, with respect to primary suture, that the wound taken after early surgical cleansing and resection is as good as sterile; and, with regard to *secondary suture*, undertaken with a wound in good condition and a purely serophytic infection, that such operative procedure, provided it leaves behind no infected dead spaces, directly contributes to sterilization. (2) It has been taught that we should judge of the fitness of the wound for closure by necro-pyo-cultures and direct microscopic examination of the pus. We have learned that it would be infinitely more reasonable to base our judgments upon the results of bio-pyo-culture. (3) It has been taught that suture cannot be successful in a wound containing a hæmolytic *Streptococcus pyogenes*. We have seen that leucocytes can, given proper conditions, successfully combat this, and of course all other streptococci; and that these conditions can be realized in connection with the suture of wounds. (4) It has been taught that for the removal of sloughs from foul wounds chemical solvents are required. We have learned that sloughs can be removed by tryptic ferment set free from disintegrated leucocytes, and that the liberation of this ferment can be greatly accelerated by breaking down the leucocytes in the discharges with hypertonic saline solution. (5) Lastly, it has been taught in connection with antiseptics that sterilization is obtainable only by continuous or very frequently repeated application. We have learned that there is nothing to prevent any part of a wound surface which has been washed quite clear of albuminous matter being sterilized by a single application of antiseptics.

2. War Scars and Their Pains: With Special Reference to Painful Amputation Stumps.—Major Edred M. Corner points out that war scar tissue is an irritant, containing contracting fibrous tissue, inflammatory foci, and pathogenic organisms. The irritation ascends the stump and starts infective inflammation in the muscles, arteries, veins, bones, connective tissue, and nerves. The pain is of composite, not necessarily nervous, origin, from the osteomyelitis of bone or the arteritis of an artery, in which case it is folly to confine treatment to the nerve trunks. In one case, in which the arm had been shattered about the elbow and amputation made below the shoulder joint, Major Corner and Professor Marinesco discovered a piece of metal about the size of a pin's head in the nerve some months after the wound had healed. These observers also noticed the frequent occurrence of dark patches on their sections. These they concluded were shrapnel pulverized by the action of the body juices on masses embedded in the wounds and carried upwards by the lymph stream. They also found particles of fibers, probably silk, which also had been carried up into the structures including the nerve ends in these painful stumps. They consider these as probably relics of the fragmentation by the body fluids of silk ligatures, carried away by the lymph stream. From all this they conclude that silk is an irritant—a kind of internal seton—some of which is carried upwards by the lymph stream and some shed outward from abscesses, sinuses, and discharges of the wound, and that war time scar tissue is unable to encapsulate an unabsorbable suture; that, therefore, silk should never be used in war wounds, the great pathological characteristic of painful stumps being the presence in them of foreign bodies. Corner furthermore calls attention to the fact that a nerve divided always regenerates. In general it regenerates so as to reinnervate the deinnervated parts. But if the deinnervated parts have been removed by amputation then the fibers of regeneration seem to innervate all structures they meet, and sooner or later they must come across the inflammation infested scar tissue, when we have the simple algebraical equation: nerve + inflammation focus = pain. The particular function of the nerve affected does not seem to matter. War tissues must therefore be done away with before much regen-

eration can take place, and this may be accomplished by heat, light, *x*-ray, radium, vibration, electricity, and ionization. Should the regenerating fibers encounter an obstruction, they form a tumor—a *regeneration neuroma*. They then flow on. If this infective scar tissue is not removed, reamputation will become necessary and, of course, will have to be done much higher up. In the nerve end the irritation may cause arteritis, endarteritis, phlebitis, lymphangitis, and thrombosis in the intraneural vessels. The irritative process travels more freely and further along the vessels than along the nerves, and the vessels should therefore be cut short at every amputation.

The Similunar Plica; a Prodromal Symptom of Measles.—E. Meyer describes a sign which he considers an even earlier one than Koplik's. It consists in a tumefaction of the semilunar fold at the internal angle of the eye. The redness of this fold is in contrast to the normal vascularization of the surrounding conjuctiva. It may happen that the fold becomes covered with minute white spots making it analogous to Koplik's sign on the buccal mucosa.

An Epidemic of Dysentery at Dresden in the Summer of 1917.—R. Lämpe sifts the data collected from an epidemic whose primal cause was the food restrictions of war and the indigestible quality of the food, particularly black bread and dried vegetables. In the resulting debility of the people, the dysenteric bacilli flourished with facility. The writer also admits the possibility of the transformation of already preexisting bacteria. The symptomatology of the epidemic did not appear to offer any particular characteristics, while of the various treatments resorted to with such drugs as bolus alba, bismuth, vegetable carbon, simaruba, rectal irrigations with tannin, antidysenteric sera, etc., bolus alba gave the best results, but could not be long continued on account of the absolute disgust which overcame the patients to its use. The writer at length employed Carlsbad salts and bismuth subnitrate. During the phase of frequent stools a coffeespoonful of bismuth was given in the morning and a dose of 30 centigrams was given six to eight times during the day. Lämpe was not able to detect any difference in the clinical evolution of the affection in the cases in which the Shiga-Kruse bacillus was found from those in which the organism was absent and thinks that it is safe to admit that in the cases he observed both direct and indirect contagion were in play.

Münchener medizinische Wochenschrift.

April 23, 1918.

The Prophylaxis of Erysipelas with Antistreptococcic Serum.—Rost having remarked the insufficiency of the various treatments of erysipelas when once developed, as well as the present frequency of this nrocess following operative work on infected wounds, has injected antistreptococcic serum at the time of the operation in cases where this complication was to be feared. Although the writer is unable to offer precise statistics, he believes that this practice has a sure effect. He thinks that the immunity thus obtained lasts for about ten days. Rost has observed reactions of the "serum disease" type following these prophylactic infections but the exhibition of calcium chloride will prevent these seric reactions, which the writer regards as anaphylactic in nature.

The Importance of Early Marriage for Repopulating After the War.—A. Ploetz in the first place proves by his statistics that marriage among young people results in greater fertility, not merely from the viewpoint of a longer duration of the child-bearing period but also for the annual percentage of births which result. Besides other factors related to late marriage (alcoholism, syphilis), late marriage appears to be one of the principal obstacles to the renewing and expansion of the population. This reasoning applies to all classes of society but is more keenly felt among the more educated. A condition *sine qua non* for rejuvenation of marriage among those belonging to the liberal professions consists in better salaries in the case of certain employees of the state (school masters, officers, assistant physicians, etc.) and above all shortening the time now required in preparatory studies. The writer advises reducing the number of school and university years and winds up with considerations on measures of a moral order, consisting in opposition to individualism and rationalism, both of which are on a wide increase.

Deutsche medizinische Wochenschrift.

April 25, 1918.

Plastic Operation on the Face for an Exceptionally Extensive Loss of Tissue.—J. Joseph offers two photographs of the patient before and after the operation to be described, which unquestionably was a brilliant bit of plastic surgery. Both cheeks, the nose, and upper jaw of the patient had been blown away by a missile. Therefore it was a question of restoring the entire middle portion of the face and in order to accomplish this, besides the prothesis of the jaw, Joseph mobilized a flap of scalp extending from ear to ear and containing both temporal arteries. At the first seance, this flap was brought forward and turned over, its raw surface being covered by Thiersch's skin grafts. At the end of a month the flap was again mobilized and again turned over, lowered and sutured on the anterior aspect of the face. The primarily under surface of the flap was thus made to form the bucconasal mucosa, covered as it was by the grafted epidermis. The scalp consequently formed the skin of both cheeks, nose and upper lip. The vitality of the tissues has remained in such excellent condition that the writer does not hesitate to say that it would be possible, if necessitated, to make a much larger scalp flap for the reconstruction of the entire face from the eyebrows to the chin. The cranial denudation was later on filled in with skin grafts and flaps made from the surrounding areas, so that only a little depression resulted from the loss of tissue required for the plastic operation.

The Radiological Diagnosis of Gastric and Duodenal Ulcer.—G. Singer notes that the diagnosis of duodenal ulcer becomes more frequent and this has revealed the fact that this pathological process has, in the past, given rise to the mistaken diagnosis of gastric neuropathies in all functional disturbances of the stomach. Singer develops his thesis by experience acquired since the beginning of the war and discusses the indications, recently developed, for radiography in gastric disorders.

Observations on the Etiology of Epilepsy, Particularly That of "War Epilepsy."—E. Redlich, after having given some more examples of epilepsy occurring on account of the war, without any recognized causal factor, concludes by admitting an "exaggerated epileptic reactivity" in certain subjects. This peculiarity enters into the class of individual variation and is not of necessity in relation to an hereditary taint or evident antecedents. It is this "reactivity" that is to be invoked in order to explain the frequency of epilepsies born from the influence of the moral or traumatic shock of war. In spite of all this, Redlich is not inclined to admit a true "war epilepsy," because such a morbid entity cannot offer a single character belonging properly to it and which could assign it to a special place among the epilepsies in general.

Disturbances of Micturition at the Front.—J. Polak's choice in the subject of his contribution to science brings to mind a poetical contribution of the late Eugene Field, "When Willie Wet the Bed," because he is quite unable to find in the diagnostic means at his disposal, likewise in modern physiological data, any explanation for the causation of the manifold forms of incontinence of urine which is frequent among the Teuton soldiers at the front. He takes the practical standpoint and divides the cases into three classes, viz.: (1) Complete incontinence, the bladder emptying

itself drop by drop, without any sensation of the need. These suojects are absolutely inapt for service. (2) Incomplete incontinence, the urine flowing only when there is a sensation of the need to empty the bladder. These subjects may be considered apt for service at the rear. (3) Pollakiuria, not a true incontinence, represented by frequent and imperious desire to void urine. This class of cases is susceptible of cure by means of special treatment (urological and neurological) so that these subjects may be entered into the active formations.

May 4, 1918.

Traumatic Gastric Ulcer.—A. Edelmann reports four instances of this much discussed subject, showing the relation of cause to effect between abdominal trauma and the ultimate development of gastric ulcer, which appears to him unquestionable. All four of the patients had developed ulcer of the stomach following upon traumatism of the abdomen in warfare without offering an apparent surgical lesion. In all four cases the lesion resulted from an exploding shell at a little distance away. Edelmann underlines the fact that these patients in which he noted the lesion were vagotonic subjects, their condition being characterized by a nervous state in which there was an excess of autonomous nervous functions.

Observations on the Etiology of Epilepsy, Particularly That of "War Epilepsy."—E. Redlich studies the possible parts played in epilepsy by such factors as syphilis, helminths, burying by bursting shell, etc. The writer has met with other cases in which the epilepsy became manifest during service at the front, although he was unable to fix upon any etiological factor. Such instances may be related to a certain disturbance of the vaso-motor system.

Study of Globular Resistance in Various Isotonic Saline Solutions.—Chauffard and Huber after a study of many assembled data state that saline solutions have in common several properties—isotonic, isosmotic, equimolecular. Does it also follow that they are isoactive chemically with reference to an anatomical element like the erythrocyte? Osmosis alone cannot explain the generality of cellular exchange. Saline solutions formed of electrolytes appear to escape the principle of equimolecularity by the more or less complete dissociation of their constitutive elements. This dissociation augments the number of molecules. In fact, the molecules in solution are dissociated into ions, water being the agent. This view of Arrhenius shows how much more complex are these phenomena than one has suspected. In addition to a molecular phenomenon like osmosis we have electrochemical interreactions between cellular elements and the media in which they live. As Starling says, in addition to osmotic or volume energy, each molecule in solution is endowed with chemical energy which does not depend alone on the number of molecules, but also on their nature. In the case of electrolytes or ionisable substances the chemical energy is measurable. Hence it would be an error to regard isotonic solutions as physiologically equivalent. Theories which are very simple are not always true. In regard to experimental hemolysis equality in osmotic tension is a protection to the living cell, but such protection is only relative and does not suppress the possibility of an injurious chemical action.

Role of the Periosteum in the Formation of Bone.—Leriche and Policard conclude that the periosteum is a physiological rather than an anatomical element. It contains two antagonistic components which, acting together, secure harmony of osteogenesis. One is responsible for growth of bone, while the other—the fibrous portion of the peritoneum—tends to limit the growth. Normally the two components are in a state of equilibrium. Surgical detachment of the periosteum ruptures the equilibrium and causes a series of phenomena of osteogenesis, whatever the subject's age. The surgeon is therefore able to create bone formation at will. This law is not peculiar to osseus tissue as we see it everywhere. The relation of periosteum to bone is analogous to that of the epidermis to the derma.

Adenoid Subjects with Pituitary Feminism.—Citelli and Caleceti refer to an earlier study of a psychic syndrome associated with adenoid. The leading features are loss of memory, somnolence or insomnia, mental insufficiency, and inability to fix the attention. This mental picture may also be seen in nasopharyngeal tumors and sinus disease, and is believed to be associated in some way with the hypophysis. In the present article they report three cases in soldiers, one of which is as follows: Soldier, aged 25, family history negative, save that a brother, aged 12, is a mouth breather and presents psychic disturbances. Has had nasal obstruction since childhood and an abscess in the right ear. He could make no progress in school, and at 14 began work in a sulphur mine. His outside life was solitary, and he slept poorly. At the age of 20 he began his military service, which was continued into the present war. He had always seemed preoccupied, and when he received a word of command would continue to repeat it lest he forget. He was rather indifferent to the opposite sex, and had had intercourse but a few times. Upon physical examination he presented hypotrichosis, his face being nearly smooth, with but a scanty growth in the axillæ and on the pubes. The absence of hair about the anus and on the perineum suggested the other sex. The head hair was fine and not overabundant. The texture of the skin was feminine. There was a suggestion of gynecomasty and feminine pelvis and hips. However, the frame was that of a well-developed male, including the genitals. From a different angle the man was a typical adenoid subject, with ogival palate and crowded teeth. The temperature and pulse having been repeatedly determined, the patient was tested for a reaction to pituitrin, an injection of which determined a slight increase of both along with sweating, restlessness, headache, palpitation, etc.

Three Cases of Epidemic Parotitis with Iridocyclitis.—Weve refers to the description by Heerfordt in 1909 of a uveo-parotid fever in which both the glandular and ocular processes pursued a chronic course. This author reported three cases of the malady which he concluded after the exclusion of lues, tubercle and pseudo-leucemia to be *sui generis*. Weve is now himself in position to report three further cases and is inclined to believe that the disease is essentially epidemic parotitis with secondary implication of the uveal tract. In other words, ordinary mumps with persistence of swelling and intraocular metastases. In the first case there was no history of exposure to mumps and no known case in the immediate vicinity, but the second case occurred after three cases had developed in the neighborhood and the third developed in a veritable epidemic of mumps. All the patients were children (under 16). If now we study the vagaries of mumps we find that sporadic cases occur and that the swelling instead of subsiding at a given date may persist for months (Osler). Various symptoms complained of by the different patients—such as pain in the joints—may occur in mumps. Of much interest are the known eye complications of mumps. These are rare and include optic neuritis with secondary atrophy keratitis and catarrhal conjunctivitis. Iridocyclitis is not mentioned, but could doubtless be masked under one of the other affections. Fuchs has seen double parotitis with lacrymal gland infection and this leads to a suggestion of Mikulicz's disease in which the parotids and lacrymal glands are synchronously involved. Now in this affection iridocyclitis has occasionally been seen, so that even if the syndromes of Heerfordt and Mikulicz are different affections there is apparently a bridge between them. We are also thrown back again on the hypothesis that Mikulicz's disease like many other rare affections is quite likely a result of lues, tubercle or other granulomatous process.

Book Reviews.

A Diabetic Manual. For the Mutual Use of Doctor and Patient. By Elliott P. Joslin, M.D., Assistant Professor of Medicine, Harvard Medical School; Consulting Physician, Boston City Hospital; Collaborator to the Nutrition Laboratory of the Carnegie Institution of Washington, in Boston; Major, M. R. C. Illustrated. Price, $1.75. Philadelphia and New York: Lea & Febiger, 1918.

In this little book the author gives, very briefly the modern ideas on diabetes and its treatment. The manual, which is quite elementary, is intended for the patient as well as the practitioner, as it is presumed that the two will cooperate. The first part gives in simple language a rapid survey of the subject, noting the most important points and emphasizing certain details. The second part contains an outline of the treatment of the more severe cases. In the third part will be found the diet tables and recipes which the author has found valuable in his daily practice. The last part contains a description of the simplest reliable tests for the estimation of sugar and acid bodies in the urine, sugar in the blood, and carbon dioxide in the alveolar air. There is a certain amount of repetition, but this is a decided advantage. Those of our readers who are acquainted with the author's larger and more complete work on the subject will be glad to know of this little book; those who do not know the larger work should certainly look at this volume.

A Manual of Clinical Diagnosis by Means of Laboratory Methods. For Students, Hospital Physicians, and Practitioners. By Charles E. Simon, B.A., M.D., Professor of Clinical Pathology and Physiological Chemistry in the University of Maryland Medical School and the College of Physicians and Surgeons, Baltimore, Md. Ninth edition, enlarged and thoroughly revised. Illustrated with 207 engravings and 28 plates. Price, $6.00. Philadelphia and New York: Lea & Febiger, 1918.

The new edition of this standard work has been thoroughly prepared; many sections of the book have been rewritten, and new matter and new illustrations have been introduced. Important new matter will be found in the sections dealing with the intestinal animal parasites, the diagnosis of acidosis, the examination of blood for transfusion purposes, and the colloidal gold reaction of Lange. As in the two former editions, the work is divided into two parts, the first treating of the technique of making the various examinations and tests, and the second giving the various laboratory findings in the different diseases. The reader may obtain some idea of the completeness of the work when he learns that the chapter on the blood contains more than 170 pages, that on the feces more than 60 pages, while that on the urine is nearly 200 pages in length. These chapters are almost encyclopedic in character. The second part of the book will prove most valuable to all practising physicians; it contains an account of the laboratory tests which may be of service in any given disease, and also shows how to interpret the various laboratory findings. The illustrations are numerous and excellent and add much to the value of a really useful book.

A Text-Book of Obstetrics. By Barton Cooke Hirst, A.B., M.D., LL.D., F.A.C.S., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopædic, and the Philadelphia General hospitals. Eighth edition, revised and reset. With 715 illustrations, 38 of them in colors. Price, $5.00. Philadelphia and London: W. B. Saunders Co., 1918.

This new edition of Hirst's Obstetrics brings up to date one of the standard works on the subject. The volume, in spite of the revision, is a little smaller than some of its predecessors. As a text-book this work has few rivals, and in some respects it is superior to its competitors. The illustrations are numerous and well executed and have always been one of the distinguishing features of this book. Another characteristic is the inclusion of such gynecological operations and procedures as are necessitated by labor and its complications. There are few works on obstetrics which have reached an eighth edition and have held their own for a period of twenty years; a book which has accomplished this may be assumed to possess unusual merits, and to be well worth the attention of the general practitioner and the medical student.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. June 1, 1918. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger.

This issue of Progressive Medicine contains chapters on Hernia, by W. B. Coley; Surgery of the abdomen, exclusive of hernia, by A. O. Wilensky; Gynecology, by J. G. Clark; Disorders of nutrition and metabolism, diseases of the glands of internal secretion, diseases of the blood and spleen, by O. H. P. Pepper; and Ophthalmology, by E. Jackson. The present number is of more than ordinary value; it contains a number of timely and useful articles, such as: Hernia in relation to the war; the relation of trauma or industrial accident to hernia; the medicolegal aspects of hernia; military surgery; and Dr. Clark's always welcome discussion of the cancer problem.

Evolution de la Plaie de la Guerre. Par A. Policard. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1918.

This title naturally suggests the reaction of a wound and the process of repair without reference to infection or the results of treatment. As a matter of fact, however, the latter are fully considered and it is not readily comprehended why the book was not termed "War Wounds and Their Treatment." The publishers' notice styles the volume a novel departure in applied physiology, but to the reviewer the chief element of novelty is perhaps the large number of microscopic sections, especially those of low powers (about 100 to 150 diameters), which may certainly serve to broaden the conception of wounds and their sequelæ for the average reader.

Manual of Vital Function Testing Methods and Their Interpretation. Second Revised and Enlarged Edition. By Wilfrid M. Barton, M.D., Author of "Therapeutic Index and Prescription Writing Practice"; Associate Professor of Medicine, Medical Department, Georgetown University; Attending Physician to Georgetown University Hospital, Columbia Hospital and Washington Asylum Hospital. Price $2. Boston: Richard G. Badger.

The progressive physician has long been acquainted with some of the functional tests. Unfortunately, a description of these tests is generally to be found scattered in the periodical literature. The author of this little volume has performed a real service in collecting the most valuable of these tests into a handy volume. That the first edition was exhausted in less than a year proves that the book was appreciated. In this new edition a few additional articles are added, so that the volume now includes a description of the Van Slyke method of urea determination, Ambard's coefficient and McLean's index of urea excretion, test meal investigations of kidney function, and articles on sphygmobolometry, sphygmobolography and energometry. The volume contains all that is of practical value on the functional tests of the liver, kidneys, pancreas, heart, and ductless glands. Clinicians and laboratory workers, alike, will find the book well worth their attention.

Reagents and Reactions. By Edgardo Tognoli, M.D., Professor in the University of Modena. Translated from the Italian by C. Ainsworth Mitchell, B.A., F.I.C. Price, $2.00. Philadelphia: P. Blakiston's Son & Co., 1918.

These are a list of reagents and reactions compiled by Dr. Tognoli. They provide a handy means to refer to the more important chemical reactions arranged in alphabetical form of the name of the chemist who first applied them. The book should be of great value to the medical man.

Society Reports.

AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS.

Eighteenth Annual Meeting Held in Philadelphia, March 29 and 30, 1918.

DR. EUGENE L. OPIE OF ST. LOUIS IN THE CHAIR.

A Simple Method of Carrying Meningococcus Cultures.—Drs. J. BRONFENBRENNER and M. J. SCHLESINGER of Boston presented this communication. Cerebrospinal meningitis had achieved the reputation of being a "disease of infants and children" on account of frequent epidemics among young individuals. With the idea of adding to the knowledge of this infection in preparation for further possible outbreaks in the spring and summer, the present study was undertaken. Meningococcus strains had always shown great specificity, and for this reason curative sera were made polyvalent. This necessitated the carrying of many culture strains in each laboratory where this work was in progress, and it had become quite a problem to carry all the strains. On account of the difficulty of isolating the meningococcus and of cultivating it on prepared media a great deal of work had been done along this line. Numerous workers had advocated various media such as serum, ascetic fluid agar, Loeffler's serum, agar from placental extract, agar from beef heart, trypsin digested, etc. The best results, however, seem to have been gained by the use of liver agar medium, originally described by Dopter. This medium, however, had great variability in quality and with this in mind the authors had worked out a modification of the preparation of the medium, in order to render it more uniform. The method was as follows: (1) A liver infusion was made, using 1,000 grams of liver to 1,000 c.c. of water. The extract was collected through a single layer of cheese cloth, boiled, and stirred continuously. The reaction was not adjusted. The mixture was then strained through single cheese cloth and a thin layer of cotton. It was then sterilized at 10 lbs. pressure for 10 minutes. (2) A 3-per cent. agar solution in water was made and filtered through cotton, and to this was added 2 per cent. peptone and 1 per cent. NaCl. The reaction was not adjusted. It was sterilized at 15 lbs. for 30 minutes. Equal parts of (1) and (2) were mixed while hot and tubed into sterile tubes. This gave a clear transparent medium with a great deal of water condensation. Meningococcus colonies grew very rapidly upon such medium, which was important for detecting carriers.

The Value of a Cooked Meat Medium for Routine and Special Bacteriology.—Dr. W. L. HOLMAN of Pittsburgh read this paper. The object of the study was to bring to notice the cooked meat medium now so widely used in the study of the anaerobic bacteria of war wounds and to show its usefulness in routine bacteriological study as well as in more special lines of research. Theobald Smith, Tarozzi, von Hibler, Robertson, and Henry had shown the value of tissue media for cultivation of many anaerobic bacteria. The meat medium used since 1916 was made from beef muscle. The meat was freed from fat and gross fibers, finely minced, ground in a mortar and mixed with equal parts of water. It was then slowly heated to boiling with constant stirring to allow the soluble albumins to coagulate about the meat particles. These coagulated albumins in themselves served as favorable medium for anaerobic growth. It was then neutralized to rosolic acid or phenolphthalein, tubed and autoclaved for one hour. Before use the tubes were always heated to 100° C. for one half hour. The seeding was done by pipette or needle and the material thoroughly mixed with the meat particles. There were no further precautions for anaerobic conditions necessary. The author said he had grown all types of anaerobic bacteria from war wounds in such open tubes and all grew equally well. Thus it was found the best medium for mixed flora of wounds. One great advantage was that it was found that products of growth did not destroy the various forms, and the medium could therefore be utilized for reisolation of bacteria that had died out, or become overgrown into other media. The "buffer" action of the meat particles in preventing extremes of reaction, undoubtedly favored symbiosis. This medium was undoubtedly the best to be had at present for growth of anaerobic and also aerobic bacteria, for storing mixed cultures as well as pure cultures, and for the differentiation of the various types.

Dr. H. T. KARSNER of Cleveland asked Dr. Holman whether the meat was made neutral to litmus. They had used it a good deal and had always made it somewhat alkaline to litmus. It was found a most remarkable medium for cultivating all of the flora out of wounds. He had never taken the trouble to heat it beforehand. So long as the meat was tender and the culture deeply implanted, growth was secured. He had been particularly impressed with the beauty of the chains of streptococci as the organism grew in the meat.

Dr. W. L. HOLMAN said in closing that the meat was used with the reaction on the alkaline side of litmus, particularly for the anaerobes. It was useful in a great many ways. They had endeavored to bring out from the wound some of the stricter anaerobes, which are always more difficult to grow. Heating the meat one-half hour before seeding gave the best conditions for growth.

The Influence of Oxidizing Substance on the Catalase Value of the Blood and Tissues.—Dr. A. ARKIN of Morgantown, Pa., presented this subject. The work might be briefly summarized as follows: Sodium iodozybenzoate, an active oxidizing agent, which had been shown to have a stimulating effect on the production of antibodies, inhibited the development of local allergic reactions, and had a stimulating effect on phagocytosis in vitro. It had no effect on the catalase value of the blood of normal rabbits. The tissues of rabbits injected with the drug showed no change in catalase value with the possible exception of the spleen in which it seemed to be increased.

Experimental Trinitrotoluene Poisoning.—Dr. S. R. HAYTHORN of Pittsburgh presented this communication. He said that all recorded attempts to produce T. N. T. poisoning, save in those in which the inunction method had been employed, had failed thus far. Recent attempts to produce poisoning through the inhalation of fumes and gases had also failed, but the conditions under which the employees of T. N. T. factories are exposed to the inhalation of fumes and dusts from that substance had never been experimentally reproduced. The acute gasings (which was such a common form in the nitrating places) was an incidental poisoning and was not due to the T. N. T. proper. By means of inunctions there had been successfully produced dermatitis, discoloration of the subcutaneous tissues, early focal lesions, and fatty changes in the liver, and positive Webster's tests in the urine had been obtained. The best results had been obtained by feeding T. N. T. either as a powder or dissolved in milk. By this means discoloration of all of the fat tissues of the body, fatty changes in the liver and kidneys, and extensive necroses of the liver had been caused, while marked blood destruction accompanied by haemosiderosis of the spleen and haemoglobinuria had been noted. T. N. T. was soluble in all of the body fluids. The author stated that the more crude products were more poisonous than the chemically pure ones. It was also likely that the variations found in the percentages of those affected in the various factories were due quite as much to the relative amounts of impurities as to the unhygienic conditions. Further experiments were advisable, along the line of discovering whether certain forms of T. N. T. were less toxic than others. If such products could be obtained, in which, at the same time, the detonating power would not be lessened, the work would have been worth while.

Dr. LEO LOEB of St. Louis said he wished to point out that it was very easily possible to produce necrosis of the liver in guinea pigs. In some respects, therefore, these animals were not favorable for experimentation. He had no doubt, however, that in this case the lesions were entirely due to the substance employed.

Dr. ROBERT A. LAMBERT of Columbia University, New York, expressed his interest in Dr. Haythorn's report. He had worked in his laboratory on the same problem for the past 6 months. His results agreed on the whole with those of Dr. Haythorn. He had produced a state

of poisoning, sometimes fatal, with definite degenerative changes in the liver cells. So far, such changes in the liver cells, analogous to toxic jaundice of munition workers, had not been experimentally produced, that is, the changes practically identical with acute yellow atrophy. Dogs were selected, as being larger, and because of the objection to rabbits and guinea pigs mentioned by Dr. Loeb. The poison was administered in four different ways: (1) feeding T. N. T. dissolved in butter; (2) inunction (T. N. T. in lanolin); (3) subcutaneous injection of acetone solution; (4) intravenous injection of an acetone solution. The last two methods were unsatisfactory inasmuch as they did not correspond to the mode of intake in man. Feeding presented the difficulty that the dogs refused the food with T. N. T. and if they took it, they vomited afterwards. However, enough was ingested to produce symptoms in a week or two. These symptoms were lassitude, weakness, diarrhea, loss of weight. Some animals died in ten days or two weeks, one survived two months. Autopsy disclosed fatty and degenerative changes in the liver, particularly in the central part of the lobule. Blood pigment was encountered in the spleen and bone-marrow. The same results followed the inunction with T. N. T., when starvation and diarrhea caused death. The urine obtained by catheterization gave an early and positive Webster's test, regardless of the mode of administration. The test was evidently a very delicate one. The reason the animals did not show toxic jaundice was most likely because they did not live long enough. In munition workers there was most likely a latent period between exposure and development of the symptoms.

Dr. M. Abbott of Montreal said that a case seen in the hospital in Montreal would be of interest in connection with this subject. The patient, a medical student, who had been working for a short time in a dynamite factory, came into the hospital with quite a mild form of toxic type of poisoning. He was discharged after a short time with the direction that he should be careful through the summer and come back for his sessional work. He returned very ill with acute jaundice, was three days in the hospital, and then died. Autopsy showed an extreme form of jaundice with pronounced cirrhosis of the liver.

Dr. S. R. Haythorn said in closing that he had obtained vomiting in the guinea pig fed with the trinitrotoluene in milk. Also there was diarrhea. There were not only lesions of the liver but the reaction of blood destruction, hemoglobinuria, and pigment in the spleen, showing that there was marked absorption.

Autopsy Service in a Military Hospital.—Dr. Howard T. Karsner of Cleveland read this paper, which summarized the findings of a service of 8 months in a base hospital of 1,250 beds and included 87 autopsies. Only 6 of these were purely medical cases, including one case of diabetes, one of malignant endocarditis, and 4 of mustard gas pneumonia. The remaining cases died of infections resulting from war wounds, most of them being multiple shell wounds. The involvement of serous cavities appeared to be important in determining the fatal issue. Gas gangrene was the cause of death in a few of the cases, being due particularly to the *Bacillus welchi*. Pyemia appeared fairly often, metastatic infection in important situations appeared also but the most common condition was septicemia as a result of infection with the *Streptococcus pyogenes*. Attention was called to the value of instituting every possible therapeutic measure to shorten the time during which a patient has suppuration going on in his wounds. It was suggested that very often amputation was much more desirable than the saving of a mutilated member, the function of which would be impaired after recovery, for if suppuration were prolonged by such treatment there would always be the danger of permanent damage to parenchymatous organs such as the heart, liver, and kidneys.

Dr. J. J. Mackenzie of Montreal said that Dr. Karsner's experience was in an area where he spent nine months at a time when there was very little fighting and few postmortems from war infections. He would emphasize the importance, in military hospitals, of the work of the pathologist and its influence upon the treatment of the cases. This was amply demonstrated in his experience in the treatment of dysentery among the soldiers.

The Agglutination of Human Red Blood Corpuscles by Horse Serum.—Drs. Herbert W. Williams and Harold A. Patterson of the University of Buffalo made this communication. Nineteen specimens of normal horse serum or antibacterial serum were tested and twelve of these produced some agglutination of human red corpuscles in the test-tubes in 1 to 20 dilutions: two sera agglutinated in 1 to 200 dilutions. Washed blood-corpuscles were used in dilute suspensions (1-100 in the final mixtures), and after incubation with the serum one hour at 36°, were allowed to stand at room temperature in a cool place, as these conditions seemed to favor the detection of small amounts of agglutinin. (In the case of three sera that gave positive agglutination, two still gave agglutination but the third and strongest serum showed no agglutination when the tubes were kept continuously at 37°, using 1 to 20 dilutions of the sera.) The last tests were only made with a single sample of blood. How far test-tube experiments might be used as an indication of what happened in the living body was uncertain, however. Experiments on laboratory animals with alien sera had given results that were inconclusive. In view of the increasing use of normal horse serum and curative sera for the infections in large doses, frequently intravenously, the possibility that agglutination of red corpuscles might sometimes occur in the body seemed worthy of attention.

Intestinal Flora in Scurvy of Guinea Pigs and Infants.—Drs. Alfred F. Hess and J. C. Torrey of New York gave this paper. A study was made of the intestinal flora of guinea pigs on a normal diet, on a diet which produced scurvy, and again on a diet which cured this disorder. A parallel study was carried out on the feces of two infants, the object of the investigation being to note whether a definite overgrowth of putrefactive bacteria could be found under these conditions in the intestinal tract. Putrefactive organisms were present only in small numbers, and were not found to increase as the scurvy progressed, or decrease as it subsided. Dr. Hess presented this study from a purely bacteriological point of view, and emphasized the fact that the amount of putrefaction, and its effect on the tissues, could be determined only by further investigation.

Focal Degeneration of the Lumbar Cord in a Case of Infantile Scurvy.—Dr. Alfred F. Hess of New York presented lantern slides of a case of infantile scurvy in a baby 13 months of age, which showed an area of degeneration of the anterior horn cells of the lumbar region. This case was the first where the spinal cord had been examined in this disorder. It was therefore impossible to say whether this was a lesion due to the scorbutic condition, or merely associated with it. Further examinations of the central nervous system were called for in similar cases.

Dr. E. T. Bell of Minneapolis asked Dr. Hess what muscular changes were associated with the lesion. The picture appeared much like the Hoffman type of progressive muscular atrophy, except that the lesion was focal, which made a marked difference. If there were progressive muscular lesions of long standing the condition might have some relation to that disease.

Dr. Oscar Klotz of Pittsburgh said that the picture shown hardly suggested bacterial invasion. Investigations upon degenerative lesions of the cord, and the central nervous system showed the focal picking out of certain areas; this was very interesting. They had come to recognize that there were regions in the nervous system which might be affected in a peculiar manner by various agents. The peculiarity to lead was an instance.

Dr. A. F. Hess in conclusion said that there were no lesions of the muscles, as in progressive atrophy. The lesions found were quite typical of infantile scurvy, and the diagnosis was clear. He was much interested in what Dr. Klotz had said, particularly since he had recently read the work of an English investigator describing his experimental study showing similar focal necroses due to various bacterial toxins. Personally he felt that the condition was not due to bacteria, but that it was toxic in origin.

Method of Isolation and Identification of Bacteria of the Colon Typhoid Group.—Dr. J. Bronfenbrenner of Boston made this report. The question of infection of food, by being handled by "carriers" was considered. It was necessary to isolate all the varieties of patho-

genic bacteria which might happen to be present in a sample of stools. It was sought to find a medium which could be prepared in large quantities for rapid work on a large scale. Difficulties in preparing such media on account of the instability of its color were encountered. After much experimentation with media it was found that a lactose agar medium with proper mixture of rosalic acid and China blue was the most suitable. This indicator left the lactose agar (if properly prepared) without change in color. The slightest amount of acid produced by bacteria stained the colony intense blue, while bacteria not fermenting lactose left the media colorless, or slightly pink. Further problems arose with regard to the identification of bacteria which did not ferment lactose. To meet this problem it was arranged in preparing the medium, that the "buffer" was adjusted so as to permit the reading of the change in reaction as early as possible. If, however, the carbohydrate medium was made with the view of keeping the cultures for a long time then a suitable increase of "buffer" would prevent the accumulation of acid.

Certain Structural Changes in Subacute and Chronic Arthritis in Horses and Cattle.—Dr. S. A. GOLDBERG of Ithaca, N. Y., stated that nonspecific forms of arthritis were apparently more common in the larger domestic animals than they were in man. The structural changes in these inflammations were in many respects similar to *deforming arthritis* in man but they had not been found in the combination that characterized deforming arthritis. Etiological factors for these inflammations were stated to be: pressure on articular ends, faulty conformation, heavy loads, strains and stretching of ligaments and tendons. Infection evidently played a part in many cases. Umbilical infection was a frequent cause in the lower animals, and the fact that this was rare in man was due to better postnatal care. The dog and the cat were found to be more resistant to ordinary infections. Pathological changes were found to be thickening of capsular ligaments and connective tissue changes. Hyperemia and exudation were found in the synovial membranes, and proliferation was also observed. Changes of the articular cartilage, on the other hand, were mostly degenerative. A diffuse superficial necrosis of the articular cartilage appeared. In the majority of cases no apparent change in the periosteum was observed. Aside from the fact that various microorganisms were found in many of the cases studied, the pathological changes in the early stages were similar to those caused by infection.

The Relationship of the Leucocyte Count and Bone-Marrow Changes in Acute Lobar Pneumonia.—Drs. R. A. LAMBERT and S. S. SAMUELS of New York City presented this paper. Dr. Lambert pointed out that the leucocyte count in lobar pneumonia might vary within wide limits. Fatally ending cases showed either very high, or relatively low counts, while those terminating favorably usually showed a count between the two extremes. Two theories had been put forth to explain the low leucocyte count: (1) the bone marrow failed to react, either as the result of some previous injury (as chronic alcoholism) or from paralysis of blood forming elements from over stimulation by the pneumococcus infection; (2) the rapid spread of the pneumonic process took the leucocytes out of the blood faster than they were introduced into the circulation from the bone-marrow; therefore, the number of circulating leucocytes might be normal or slightly increased, even though the output from the bone marrow might be exceedingly high. There was still a third theory which might account for the phenomena, namely, that the leucocytes might be forming in some other organ; for instance, the spleen. Dr. F. A. Evans had pointed out that the gray, acute, splenic tumor of lobar pneumonia contained numerous myeloid cells, as indicated by the oxydase reaction, thus indicating a probable source of some cells of the pneumonic exudate. In a study of cases of lobar pneumonia which had come to autopsy, the authors made records of the leucocyte counts and the bone-marrow changes correlated. Specimens of bone-marrow were stained and studied. The summary of results was: Parallelism of leucocyte count and degree of hyperplasia of the marrow found in only half the cases; few showed inactive marrow and leucocyte counts above normal; on the other hand there were cases where the leucocyte count was low during life, but a hyperplastic marrow was found post mortem. One explanation of this might be the formation of leucocytes in the spleen or some other organ; a second, a hyperplasia of the marrow of the flat bones. The cases of hyperplasia of marrow with low leucocyte count were not easily explained. One could not prove that there was a rapid drainage of leucocytes out of the circulation.

Studies on Bacteriemia in the Agonal Period.—Dr. DEW. G. RICHEY of Pittsburgh reported observations on blood cultures taken at the time of death from the peripheral circulation of consecutive cases. In all, 206 cultures were examined. Seventy-six (36.8 per cent.) were positive and 130 (63.2 per cent.) were sterile. The pneumococcus was found on 32 occasions, or in 50 per cent. of the cases clinically diagnosed as acute lobar pneumonia. *Pneumococcus mucosus* was isolated five times. *Streptococcus hemolyticus*, as a class, was obtained in 27 instances. *S. viridans* in 3. *Staphylococcus pyogenes aureus* in 7, while the gonococcus, *Micrococcus pharyngis siccus*, *B. coli communior*, and *B. typhosus* were each found once. *Streptococcus pyogenes* comprised two-thirds of the hemolytic streptococci, while *S. anginosus* and *S. subacidus hemolyticus* were next in order of frequency. Out of twenty-five cases of periotonitis, only four yielded a positive culture. The acute traumatic (non-infectious) deaths gave positive findings in less than 3 per cent., whereas 36.3 per cent. of the chronic wasting diseases showed a bacteriemia. Sterile cultures were encountered in all cases of diabetes mellitus. In twenty-four instances, both ante mortem and immediate post mortem, blood cultures were taken. Eighty-three per cent. of these showed identical findings and 17 per cent. yielded organisms which were absent during life. Comparisons were also made between immediate post mortem blood cultures and cultures taken from the heart's blood at autopsy. Sixty per cent. showed the same results, and in 40 per cent. an altered bacterial invasion occurred. Cocci played the leading role at all times. Bacilli were proportionately increased in the autopsy cultures. The technique for cultivation did not include anaerobic methods.

Transplantation of Tissues into Nearly Related Members of the Same Family.—Dr. LEO LOEB of St. Louis presented this study. It was desired to know whether in transplanting tissues from parents to children, the tissues would behave in certain offspring like auto and in others like homeotransplants. Two sets of experiments were made. In one various organs were transplanted, either from parents to children, from one member of a fraternity to another, or from offspring to parent. Homeotransplants were also made. The results of both sets of experiments agreed. In the large majority of cases intermediate results were obtained, ranging between effects obtained between auto transplants on the one hand and homeotransplants on the other. In regard to the character of tissue planted, a few interesting facts were observed. Liver tissue was found to survive and even moderately proliferate after transplantation. Spleen remained alive in many cases. The uterus and ovary of the rat were readily transplantable. Lutein tissue might form anew in the ovary, and some eggs were found to withstand the effects of transplantation. The ovary of the guinea pig was not so easily transplantable as that of the rat. The homeotransplant gave results much more frequently than other varieties. Transplantation into relatives gave intermediate results.

Immunity and Tissue Transplantation.—Dr. LEO LOEB of St. Louis also made this presentation. Previous studies by the author showed that after homeotransplantation of certain normal tissue a lymphocyte reaction occurred. This was also present in homeotransplantation of tumor tissue in cases in which the compatability between transplant and host was not complete. Following a second transplantation of the tumor into the same host the lymphocyte reaction appeared earlier. In other cases, it was stated, a lymphocyte reaction might be absent after a first transplantation, but appeared after preliminary inoculation with modified tumor material. This would indicate that the reaction of the host towards a transplant is altogether a

response to the development of immunity, the lymphocytes being attracted by immunohomeotoxins and not by homeotoxins that form as a result of disturbed cell metabolism through incompatibility between host and transplant. A study was therefore undertaken to determine whether after grafting of tissue, or second inoculation of the same tissue, the lymphocytic reaction would be noticeably accelerated. A series of experiments were made in which thyroid of the guinea pig was homeotransplanted successively into the same host. The first transplant showed lymphocytic reaction, but at this time the second transplant was almost free from lymphocytic infiltration. In some cases, however, it would seem that the first transplantation might increase the lymphocytic infiltration in the second piece. Transplanted thyroids tended to disappear at an early date, but whether this was due to an immune reaction on the part of the host could not be determined. It was considered probable that the lymphocytic reaction was a response to the primary homeotoxins, and not merely to the effect of immunohomeotoxins, although the latter might cause an additional reaction.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, March 27, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

Symposium on Nephritis: Symptoms and Diagnosis.—Dr. DAVID RIESMAN under this caption designated hysteria and uremia as two diseases manifesting themselves in protean ways. The greater frequency of uremia than of true hysteria emphasized the importance of a knowledge of its peculiar habits. He observed that while the cause of uremic poisoning was not known the fact of its exerting itself largely upon the central nervous system was well known; also that every one with hospital experience was familiar with the difficulty in a case of coma in determining the cause. No definite earmarks attended the comas of the various infections. A recent case was cited in which this difficulty was encountered in deciding between uremic coma and coma of acute cerebrospinal meningitis. Alcoholic coma and the coma of brain injuries frequently presented difficulty in differentiation from uremic coma. Catheterization and examination of the urine in such a case were regarded as of foremost importance. Enlargement of the heart and hypertension were said to point toward uremia; the eyeground changes were also mentioned as of valuable differential import. Mention was also made of the difficulty of differential diagnosis of uremic hemiplegia and of uremia aphasia. Those trained in the Philadelphia Hospital would remember the frequency with which a case diagnosed as apoplexy would at autopsy show no hemorrhage in the brain. Uremic hemiplegia was transitory in character with a tendency to recover. There was nearly always hypertension with cardiovascular changes of chronic Bright's disease and while the problem presented was that of a poisoning of the nerve cells, or of vascular crises in the brain, the transitory character of the picture might be compatible with either condition. The nervous condition of uremic headache might be the only condition of which the patient complained, and this so intense as to suggest brain tumor. Severe neuralgias referable to uremic intoxication were also mentioned. Uremic narcolepsy also was referred to as presenting difficulties in diagnosis. In a case brought into one of the hospitals sleep had been exactly like that produced by drugs. Autopsy showed the kidneys to be not much larger than a silver dollar; the only symptom, however, had been the narcolepsy lasting throughout six days. Uremic dysentery, though of rare occurrence, had been observed. Another manifestation of uremia was the so-called hemorrhagic diathesis, in which a patient would suddenly bleed from the mouth and nose and perhaps from the bowel, with patches of hemorrhage showing in the skin. In all such cases under Dr. Riesman's observation there had been the contracted kidney with high blood pressure and injured heart. In one case of uremic pericarditis there had been shortness of breath with symptoms of mediastinal tumor; tapping showed hemorrhagic fluid in the pericardium; at autopsy chronic interstitial nephritis only was shown to have been present. The diagnosis of uremia and of Bright's disease in general was to be made not upon one element but by the consideration of many. Urinary analysis might be misleading; the author had seen cases of Bright's disease with no albumen; greatly contracted kidney might be present with low blood pressure. A most valuable point observed was, that with the albuminuria of heart disease the urine was nearly always highly colored and contained a large amount of urates; the albumen was small in amount and casts few. It would, however, often test the skill of the best men to determine whether a given case was one of Bright's disease with cardiac failure, or purely a heart condition.

Functional Tests of the Kidney in Diagnosis and Prognosis.—Dr. O. H. PERRY PEPPER pointed out the following three difficulties in the study of kidney by functional tests: (1) The complexity of the kidney function; (2) the present lack of knowledge regarding the mechanism of urinary secretion; (3) the importance of extrarenal factors. Not only should the quantitative appearance of the ingested substance be measured but consideration be given the time relation, since even a markedly diseased kidney would always eliminate the increased amount of water, salt or urea if given time. It was not necessary, he observed, at this day again to kill the dead by referring to the entire usclessness of estimations of urinary urea if unaccompanied by exact control of the intake of all protein food and of the nitrogen loss in the feces. The extrarenal factors were too many for any reliance to be placed upon the test, except under extremely favorable conditions. The separate tests of the ability of the kidneys to dispose of known amounts of water, protein and salts might be combined and the patient placed on a diet containing known quantities of these substances and the results observed. This, however, was usually to be done in conjunction with studies on the blood. The determination of the freezing point and the estimation of urinary toxicity were other tests mentioned, not, however, widely employed. The blood sooner or later showed the results of any depreciation of renal activity. Attempts had been made to express the relationship of the urinary urea and the blood urea in a formula which would give the functional efficiency of the kidney in mathematical terms as an index. None, however, had proved wholly satisfactory and the plan was scarcely one for general clinical use. Another group of tests mentioned was that based upon the introduction into the body of some substance foreign to the organism but which is eliminated by the kidneys and of which it is possible to determine the rate and quantity of excretion. Of the various tests the three of special usefulness were said to be (1) The testing of the ability of the kidneys to eliminate water and to dilute or concentrate the urine; (2) The estimation of salt test; (3) The estimation of blood urea nitrogen; (4) The phthalein. Diagnosis by functional test might be considered from (1) The ability of the kidney to perform a given function; (2) an estimate of the degree of renal impairment by nephritis by one or more tests; (3) an estimate of the patient's condition at the time; (4) conclusions concerning the anatomical lesions in the kidneys. This, however, could not be successfully done with the present knowledge of the subject. The test of provoked polyuria was said to be of chief value in the recognition of acute nephritis, simple degenerative nephritis and of passive congestion of the kidneys. The test of chloride elimination often gave the earliest evidence of impaired renal function. The phthalein test Dr. Pepper regarded as the best all-round test of renal function and said there were few renal diseases in which it did not give a fairly true estimate of the renal function. Its especial value obtained in chronic glomerulonephritis. The tests mentioned were regarded as aids in prognosis only as they led to a correct diagnosis; a zero phthalein might occur in an acute nephritis and recovery ensue. It might also appear as a warning of imminent fatal uremia. In prognosis and for the control of treatment the author said that the functional tests must be repeated at intervals to obtain the best results. Emphasis was placed upon the importance of carefully excluding extrarenal factors and of always interpreting the tests in conjunction with

routine study of the urine, the blood pressure, and the patient.

Treatment of Nephritis.—Dr. WILLIAM E. HUGHES outlined the picture of Bright's disease as a condition due to retention of poisons, deterioration of the blood, interference with function of various organs and changes in the circulatory apparatus. To be remembered was the fact that the crippled condition of the kidney is aggravated by attempts to secrete even a normal amount of excrematous material. Treatment should include the attempt to prevent ingestion of further poisons, to take as much work off the kidneys as possible, to stimulate faulty function of other organs, to restore the blood condition, to minimize the injurious effects of circulation, and possibly to stimulate the faulty kidney to renewed activity. In the question of treatment food was regarded as the most important. Milk was probably the least injurious food. This might be taken as sweet milk, buttermilk, whole milk, or skimmed milk, and in some cases of Bright's disease such a diet was to be reverted to as the ideal. Meat was regarded as the most injurious form of diet because of its high nitrogen content. The nitrogenous foods apparently poisoned the most seriously and permanently. A certain amount of nitrogenous intake, except for a short period of time, was of course necessary, and for this eggs, rather than meat, might be adopted. Dr. Hughes' practical experience had been that a moderate amount of salt in the diet was not harmful. In the use of water he thought the tendency was to be extreme; by increase of the watery content of the blood a secondary danger to the kidney function was produced by the consequent rise in blood pressure. Effervescent beverages were said to hold a certain element of danger in their stimulative character. The state of the digestion was regarded as of exceeding importance in Bright's disease and to it treatment should be directed with the closest attention since through absorption of toxins in the intestinal tract additional irritation in the kidneys is brought about. Intestinal antiseptics Dr. Hughes had found to be of slight value; of these calomel was probably the best. Colonic irrigation was worthy of consideration. The poison produced by fatigue was mentioned among those operative in the production of Bright's disease or in its aggravation. In no other class of disease was the character of the wearing apparel believed to be of so much importance; woolen, of proper weight, worn the year around he believed served an exceedingly useful purpose. In climate California preferably and secondly Florida probably offered the best conditions for the patient. While fresh air and plenty of it were of great value, not infrequently an exacerbation of Bright's disease might be traced to too light bedclothing and too much fresh air at night. Emphasis was placed upon the importance of the skin circulation which was to be favorably influenced by baths and massage to a moderate degree. Anemia as one of the ill effects of nephritis should always be borne in mind. The drug of greatest value was iron; pylocarpin in small doses was also employed. The dropsy of Bright's disease was said to be in no way different from the dropsy in other affections; there were present the diseased vessels, poor heart power, and wrongly mixed blood. Of cardiac stimulants digitalis was regarded as the best. It was to be remembered that many cases of apparent apoplectic "stroke" were really cases of uremia, and that in such instances vigorous treatment must be directed to the kidneys. Work, so far as possible, should be taken off of the kidneys, and the intestinal tract should be cleaned. In the presence of much hypertension, if the patient were fairly well nourished and not particularly anemic he should be frequently bled.

Dr. M. HOWARD FUSSELL believed with Dr. Pepper that the use of the term "nephritis" as a substitute for Bright's disease, which was applied to many cases of nephritis, would be advisable. To the layman the name, Bright's disease, carried the idea of an absolutely fatal condition. It was well known that many cases of nephritis, if not curable, did not bring death in any short length of time. Although, as Dr. Riesman had said, in the vast majority of the arteriosclerotic types uremia might be easily recognized by the cardiovascular changes, in acute nephritis these changes were not present. Hemiplegia it had been observed sometimes persisted until death ensued. One case cited was that of a woman in the Episcopal Hospital with typical interstitial nephritis. She did not seem to be very ill but developed a leftsided hemiplegia. Death followed, due in Dr. Fussell's opinion, to apoplexy, but autopsy revealed no sign of thrombus, simply the presence of the sclerotic arteries. Reference was also made to a case in the University Hospital which in Dr. Fussell's opinion had a bearing upon Dr. Riesman's statement that in treatment it made little difference whether the arteriosclerotic condition be recognized as the basis of certain cases of nephritis. The case presented an excellent example of nephritis due to a general arteriosclerosis. There had been dyspnea with recurring attacks of edema of the legs. The arteries had the appearance of pipe stems. The man was 65 years of age, had polyuria with low phthalein output. From the results of treatment by rest and elimination the case was in all probability one of arteriosclerosis; it was not Bright's disease. He believed it a great mistake from the standpoint of treatment to regard such a case as nephritis. Such a patient with the rest he would have if placed in an old man's home would live for many years. He emphasized the fact that albuminuria did not always mean nephritis. It was also true, unfortunately, that a great many physicians did believe that albumin in the urine proved the presence of nephritis. Notwithstanding the disappointments from the removal of teeth and tonsils for the elimination of foci of poisons causing nephritis, search should be continued for such foci, but there should be increase of knowledge of the proper method of dealing with teeth. Dr. Fussell believed that in the treatment of nephritis each case was a law unto itself. With some patients, meat, however slight in amount, seemed to act as an actual poison. In acute nephritis diuretics were regarded as absolutely harmful. Absolute rest should be enjoined and the use of digitalis in the failing heart.

Dr. WILLIAM DUFFIELD ROBINSON emphasized the necessity of study by every method of research to determine the cause of nephritis. Much could be accomplished he believed by a proper dietary. One day of starvation a week was advocated, with the intake, however, of the usual amount of fluids. Great reliance was placed upon pylocarpin in the treatment of nephritis. The essential point was to seek the cause of the abnormal content in the blood of nephritis.

Dr. MOSES BEHREND said that any disrepute into which the operative treatment of nephritis might have fallen was probably due to the fact that most cases were brought to the surgeon too late and that the cases were not properly selected. Cases of chronic interstitial nephritis did very badly as did those of interstitial nephritis in the aged on account of the arterial changes and the changes in the kidneys themselves. The most favorable cases for operation were those of acute parenchymatous nephritis. The best results had been obtained by Edebohls and Lloyd. The former had operated on about 110 cases and the latter, 25 or 30. They give a mortality of 10 per cent and claimed a cure in 33 per cent of their cases with improvement in 43 per cent. This was an extremely good record; most of the cases were well selected. His own experience had not been at all satisfactory. He had operated on six cases; three were of the chronic parenchymatous type. The last case was that of a child of six years; death followed in from 24 to 36 hours. The case was an extreme one and operation was the last resort. He had operated for bichloride poisoning, stripping the kidneys, but the patients died as they usually did in severe bichloride poisoning. About 1912 the Editors of the *Medicale Clinique* had sent a letter to the various surgeons. Favorable reports had been received from Thiersch. Other operators reported no results. In operation for eclampsia the best results had occurred after labor. Before the puerperium the results were for the most part fatal. Litchfield's mortality was 1.73 per cent in 53 cases. Many writers, especially Lloyd, had said that a fibrous capsule redeveloped after decapsulation of the kidney and that this fibrous capsule was just as bad as the original capsule. This was denied by another writer. Opportunity for reoperating on these cases was naturally not very good. E. H. Goodman had noticed a rapid fall of blood pressure after decapsulation.

Stated Meeting, Wednesday, April 10, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

SYMPOSIUM: THE MODERN TREATMENT OF BURNS AND LEG ULCERS.

Treatment of Burns by Exposure to the Air and the Application of Dichloramine Through Paraffined Mosquito Netting.—Dr. WALTER ESTEL LEE and WILLIAM F. FURNESS presented this paper. They quoted Stewart's definition of an ideal dressing for severe burns, one "that would be (1) aseptic or (2) mildly antiseptic, (3) that would provide free drainage, (4) that would not macerate or (5) stick to the tissues, and (6) would not necessitate frequent changing." Still another provision which Dr. Lee thought might be added was one which should minimize the abnormal radiation of body heat from surfaces devoid of the protection of the skin and subcutaneous tissues. There was not at the present, the author said, any one treatment of burns meeting all these conditions, although ambrine and many forms of paraffin films at present in use did fulfill some of these requirements. The recent interest in paraffin film treatment had induced many surgeons to abandon a method which for some time had given excellent results, *i.e.* the exposure of the burnt surfaces to the air. The open-air treatment of burns, in Dr. Lee's opinion, more nearly met the theoretical requirements of an ideal dressing than any other which had been proposed. Of this method the author suggested the following modifications: The covering of the entire burnt area and a generous portion of the surrounding skin with a single layer of mosquito netting previously impregnated with paraffin wax, the netting being held in place by single layers of a circular turn of gauze bandage or by adhesive strips applied over the netting and the uninjured skin (never over the burnt area). Such a dressing was aseptic, and the large open meshes provided perfect drainage for the wound secretions to the outer surface of the netting. When the scab formation on the outer surface of the netting interfered in the slightest way with the drainage of the wound secretions it could be completely and painlessly removed by lifting the non-sticking paraffin net from the surface of the wound, usually once in twenty-four hours. The paraffin netting, it was said, rarely adhered to the wound surface, but a generous spraying with sterile paraffin oil would always loosen it. The only remaining condition to be met to have the air treatment fulfill all the requirements of the ideal dressing was the use of an antiseptic. In this connection Dr. Lee said that a 1 or 2 per cent. solution of dichloramine-T dissolved in chlorinated paraffin wax (after the method of preparation proposed by Dakin and Dunham) could be used on burnt surfaces without causing any objectionable subjective or objective irritative phenomena. This oil solution could be readily applied in the form of a spray (at the room temperature no heating was required as with the paraffin films) to the entire burnt surface before the paraffin net dressing was applied, and subsequently through the meshes of the net onto the surface of the wound, if for any of the above mentioned reasons it was unnecessary to remove the dressings each day. This modified air treatment of burns had been employed upon eighty-six cases at the Pennsylvania and Germantown hospitals during the past seventeen months. Dr. Lee observed that with this they had felt that because of the surprisingly small degree of infection occurring in the wounds these had healed more promptly and with more satisfactory scars than with any other method heretofore used. An outline was given of the preparation of the paraffin mosquito netting used to minimize the sticking of the dressings to and permit the drainage of the discharges from the surfaces of the wounds and extensive burns.

The Treatment of Burns.—Dr. ROBERT PERRY CUMMINS said that in the steel industry almost every type of burn was seen, the most common being those caused by molten metal splashes coming in contact with the tissues, those setting fire to clothing, and those due to back drafts from furnaces. As regarded treatment, burns should be regarded as infected wounds. To be considered also were shock, the question of primary dressing, the postinflammatory stage, and the sequelæ. For the treatment of shock Dr. Cummins placed more reliance upon the use of adrenalin and ergot than upon strychnine and digitalis. Caution against overstimulation, however, was given. For the cleansing of the wounds he had found high-grade benzine his best agent. He used warm sterile dressing or boric or physiological salt solution, changed once or twice every twenty-four hours, continued for three or four days. In the healing period the treatment with ambrine or one of its substitutes, or the open-air method, had given the best results in his hands. In the case of the ambrine treatment he would suspend its use for a few days that the wound might be freed of pus by the application of an antiseptic such as dichloramine-T. Dr. Cummins was decidedly opposed to the exclusive use of the ambrine method in burns of large area; also he would not employ it in a sloughing area. Exuberant granulations he believed should not be cauterized since these were soon strangled by the elements of regeneration of the skin. The absence of hard, poorly nourished scar tissue was mentioned as a striking characteristic of the ambrine treatment. The open-air treatment he had found more satisfactory in hospital than in ambulatory cases. Reference was made to the important role of splints, postures, and passive motion in scars and contractures likely to cause physical deformities, and in the treatment of the usually complicating toxic nephritis emphasis was laid upon the importance of an abundance of concentrated liquid food and water, stimulation, and elimination by every possible avenue. The prognosis was regarded as difficult and uncertain until recovery was well advanced. With alcoholics the chance of recovery in extensive burns was slight. The value of careful surgery and technique equaled that of the dressings.

Iodine Fumes in the Treatment of Ulcers.—Dr. JOHN J. GILBRIDE said that about a year and a half ago, having read in the *Journal of the American Medical Association* of the satisfactory results in treatment of ulcers with iodine fumes, he had employed this method in a severe burn of the leg from a hot water bottle in a patient who had had an appendectomy. The burn had resisted the ordinary treatment given for a month or two. At the time of the first application of the iodine fumes the ulcer was about three-quarters of its original size. One subsequent treatment was given and in a week following the ulcer had completely healed. He had since used the fumes in four other cases of burn with most satisfactory results.

Treatment of Leg Ulcers.—Dr. PENN-GASKILL SKILLERN, JR., in this communication, stated that the principles of the treatment of ulcer included sterilization of the ulcer and support of the part. Since congestion was the first stage of inflammation, the patient should be put to bed and the limb elevated to an angle of 20°. Sterilization of the wound should then be effected, which was best accomplished by the use of dichloramine-T. Following the application of a 20 per cent. solution of dichloramine-T, the paraffined wide-mesh mosquito netting described by Dr. Lee was to be placed over the area and secured at the edges with adhesive plaster. The next dressing was made in from twenty-four to forty-eight hours and consisted of a 5 per cent. solution of dichloramine-T. If the ulcer was large, skin grafting might be needed, the best method of which was carried out by Steele in 1870 and which utilized a greater thickness of skin giving a graft from the size of a pea to that of a finger nail. These grafts took hold and made a more pliable scar. The treatment subsequent to the skin grafting was the same almost as before, that by the open method. A basket of wire gauze was placed over the open wound and the graft allowed to heal underneath. The best treatment for a small ulcer, practically sterile with healthy granulations, when the patient was able to be up and about, was said to be that proposed as far back as 1776 by an English surgeon and revived recently, consisting of the application of imbricated adhesive plaster strips two-thirds around the limb from below upward in the direction of the venous current. These strips supported the edge of the ulcer, compressed it, and kept the blood out of the edge, thus preventing the granulations from becoming edematous. Discharge was thus reduced to a minimum by means of the compression, and calomel powder dusted on kept the

wound dry. If there happened to be a concavity between the floor of the ulcer and the surface of the leg the compression by the adhesive plaster strips could be transferred to the base. In certain cases of simple ulcer in which this method was not effective others might be used, the simplest of which was the Nusbaum operation. In addition to local treatment there must sometimes be exposure of the nerves supplying the ulcer area. Dr. Skillern emphasized that in the treatment of leg ulcer it was essential to remember the underlying congestion and the other fundamental etiological factors involved.

Dr. Edward J. Klopp stated that he had had opportunity to see Dr. Lee's method for the treatment of burns and believed it to be the best in vogue. His experience with the ambrine treatment had been limited, but disappointing. For the removal of the carbonized tissue in the third degree burn he believed that the dichloramine-T was probably not necessary. The method formerly employed had been the use of salt solution. Most of the textbooks gave as one of the best methods that of immersing the patient in a tub of warm salt solution at a temperature of 100° to 105° F. Unfortunately, in the majority of instances the water was not maintained at this temperature and the already shocked patient was further depressed. To facilitate the removal of carbonized tissue when the patient was anesthetized and to remove the tissue with the forceps, the surface was covered with narrow strips of sterilized gauze separated about ¼ inch. The surface was then covered with gauze saturated with warm sterile salt solution. The dressing could be changed and warm salt solution added without interfering with the wound. Dr. Klopp said he had nothing to offer that would take the place of the dichloramine-T. Concerning the end results he observed that it was sometimes several years before the maximum contraction of a scar was known. He was of the opinion that in the presence of a large burnt area with healthy surface, skin grafting should probably be attempted because it expedited matters. Here, of course, the method of choice was the Thiersch procedure.

Dr. William L. Clark said that the ulcers which he saw were usually advanced cases in which ordinary methods had failed and which were sent with the idea that electricity might be helpful. He had had much success, also some dismal failures. The diagnosis of the ulcer was of first importance. Syphilitic ulcer had been referred for epithelioma; epithelioma, for simple sluggish ulcer. For the different types different treatment was required. He had found that various physical measures often did good. The principle on which electricity was used was first, destruction of the granulations; second, sterilization; third, relief of passive congestion.

Dr. Kate W. Baldwin had found nothing to be more soothing in burns and giving more rapid healing than the application of the violet ray of moderate strength. The value of the treatment had been beautifully demonstrated in a child brought to the hospital in whom one-third of the surface of the body had been burned. The patient had been treated outside until it was in a septic condition. The child was placed on the table and without an anesthetic the moderate current was applied. Care had been observed to put the electrode in contact before turning on the current. The child went to sleep and remained asleep while the application was made over the entire surface involved.

Dr. Moses Behrend observed that the treatment of burns with ambrine had given good results in his hands. The scarring he had found to be as soft following the use of ambrine as that following dichloramine-T. He believed, however, that the dichloramine-T was the better method because of its antiseptic quality and because of the fact that the ambrine retained the discharges for quite a long time.

Krönig's Latest Results from Cancer Operations.—According to one of Krönig's assistants many cases of cancer treated by the knife at the Freiburg Gynecological Clinic have been followed up for 10 years with the discovery that only 5.2 per cent. of the women had survived that period. Hence Krönig is henceforth for *x*-ray therapy.—*Correspondenz-Blatt für Schweizer Aerzte.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

December, 1917.

ANATOMY.

1. Define marrow, periosteum, compact and cancellous bone, epiphysis, diaphysis.
2. Bound the superior carotid triangle, and name the contents of same.
3. Name the organs of generation in the male and female, and describe the ovary.
4. Define hernia, and name and locate all hernias which occur in the abdomen (not traumatic).
5. State what muscles enter into the formation of (*a*) anterior wall and (*b*) floor of pelvis.
6. State definitely the result of cutting in living subjects the following nerves: Radial, peroneal, pudic, anterior femoral (below Poupart's ligament).
7. What anatomical structures pass through the sphenoidal fissure (foramen lacerum anterius)?
8. Name the salivary glands, and locate the orifices of their ducts.
9. Through what vessels does blood pass in going from the spleen to the under surface of the middle toe.
10. Name bones and ligaments entering into formation of the ankle joint.

PHYSIOLOGY.

1. State causes of pressure in the arteries, capillaries, and veins.
2. Name some of the bodily states which lessen the alkalinity of the blood.
3. Describe the process of osmosis and give examples in the human economy.
4. (*a*) Name the secretions of the alimentary canal, their reactions and functions. (*b*) Name the active principles of the digestive secretions.
5. (*a*) Describe bile and its uses; where first found; trace its course. (*b*) Name the bile salts.
6. State the general classes into which foods are divided, and give examples of each.
7. (*a*) What are the functions of the skin and its appendages? (*b*) What matters are excreted by the skin? (*c*) How may the function be affected as to the amount of excretions?
8. (*a*) Describe the functions of the kidneys. (*b*) Do both kidneys constantly act? (*c*) How does the impairment of the functions of the kidneys affect that of the skin and lungs? (*d*) Give the variations within limits of health in the specific gravity of urine.
9. Describe nerve-cells and fibers.
10. (*a*) Define reflex action, and give example. (*b*) Give illustrations of morbid reflex action.

CHEMISTRY.

1. Describe phosphorus, and name and give formula of three of its compounds.
2. Why should solutions of silver nitrate not be employed after irrigations with salt solution? Illustrate by formula.
3. How is chlorine made, and what are its chemical properties?
4. What are simple and what are compound proteins?
5. What is glucose? Why is it sometimes employed in solution intravenously?
6. Name three hydrocarbons, and give formula. Name three carbohydrates, and give formula.
7. What is Fisher's solution? What is its chemical effect when administered by the vein?
8. Describe two important chemical tests used in examining the stomach contents.
9. Describe two important chemical tests used in examining urine.
10. What chemicals are used in purifying water for drinking purposes, and how are they employed?

ANSWERS.

ANATOMY.

1. *Marrow* is a substance found in the marrow canals of long bones and the medullary spaces of cancellated

bone, and in the Haversian canals. It is composed of a fibrous matrix with blood vessels and myelocytes.

Periosteum is a fibrous, vascular structure covering bone (except where there is articular cartilage).

Compact bone is bone in which the constituents are so closely packed together that the bone appears (macroscopically) dense and like ivory.

Cancellated bone has an open or porous appearance.

Epiphysis is a process of bone which has a secondary center of ossification, and which is temporarily attached by cartilage to the principal part of the bone.

Diaphysis is the shaft of a long bone.

2. The *superior carotid triangle* is bounded, *behind* by the sternomastoid; *below* by the anterior belly of the omohyoid; and *above* by the posterior belly of the digastric.

The *superior carotid triangle* contains: Termination of common carotid, external and internal carotid arteries; superior thyroid, lingual, facial arteries and veins; internal jugular vein; vagus, superior laryngeal, hypoglossal and sympathetic nerves; upper part of larynx, and lower part of pharynx.

3. *Organs of generation in the male:* Testes, penis, prostate, Cowper's glands, seminal vesicles, vasa deferentia.

Organs of generation in the female: Ovaries, Fallopian tubes, uterus, vagina, mons Veneris, labia majora and minora, clitoris.

The *ovaries* are two in number, and correspond to the testes in the male; they are of a flattened ovoid form, vertically placed in the posterior part of the broad ligament. By its anterior border the ovary is connected to the broad ligament, and by its lower pole to the uterus by a proper ligament, extending to the superior angle of the uterus, and called the *ligament of the ovary.* The lateral surfaces and posterior border are free. The superior pole and posterior border are embraced by the Fallopian tube; on its inner surface it is in relation with small intestine in Douglas' pouch, and externally lies in a peritoneal fossa between the external and internal iliac vessels as they diverge. The vessels enter the hilum at the attached anterior border. —(*Aids to Anatomy.*)

4. A *hernia* is a protrusion of part of the parietal peritoneum, through some weak point in the abdominal wall, in the form of a sac; in this sac may be a portion of the omentum, small intestine, or occasionally some other abdominal organ.

Varieties of abdominal hernia (not traumatic):

1. Inguinal
   - Oblique
     - Acquired
     - Congenital
     - Infantile or encysted
   - Direct
     - External
     - Internal
   - Interstitial
     - Intraparietal
     - Interparietal
     - Extraparietal

   [Incomplete, or Bubonocele.]
2. Femoral
3. Umbilical
   - Congenital
   - Of infants
   - Of adults
4. Ventral.

The *inguinal* occurs in the inguinal region, above Poupart's ligament; the *femoral* in the femoral region, below Poupart's ligament; the *umbilical* in the region of the umbilicus; the *ventral* (generally) in one or more of the muscles of the anterior abdominal wall.

5. *Muscles entering into formation of anterior wall of pelvis:* Rectus abdominis, pyriformis, transversalis, external oblique and internal oblique.

Muscles entering into formation of floor of pelvis: Transversus perinei, compressor urethræ, accelerator urinæ (or sphincter vaginæ), erector penis (or clitoridis), levator ani, and coccygeus.

6. *Section of the radial nerve* (B. N. A. term for the *musculospiral nerve*) causes: (*a*) *Anesthesia.* If the nerve is divided in the upper third of the arm—*i.e.*, above the origin of its external cutaneous branch—there is loss of both epicritic and protopathic sensation over the radial half of the dorsum of the hand, of the epicritic a little more than of the protopathic. Section of the radial nerve in the upper third of the forearm causes no loss of sensation; but section of the lower third causes a limited loss of epicritic sense over the back of the thumb. (*b*) *Paralysis* of (1) the extensor of the forearm (triceps), hence the forearm can only be extended by its own weight; (2) the long and short supinators, hence the hand is pronated; (3) the radial and ulnar extensors of the wrist, hence wrist-drop; (4) the extensors of the fingers and thumb, which either hang limp and motionless or may be bent up into the palm from the unopposed action of the flexor muscles.

Section of the peroneal nerve (B. N. A. term for the *external popliteal nerve*) causes anesthesia of the dorsum of the foot and a varying portion of the front and outer side of the leg, together with paralysis of the extensor and peroneal groups of muscles; and from the contraction of the unbalanced opposing groups, the paralytic form of talipes equino-varus results.

Section of the pudic nerve causes pain in perineum, penis, scrotum, buttocks, down the thigh; priapism, incontinence of urine; and interference with the action of the levator ani, compressor urethræ, ischicavernosus, bulbocavernosus, and transversus perinei muscles.

Section of the anterior femoral nerve below Poupart's ligament (B. N. A. term for *anterior crural nerve*) causes paralysis of the quadriceps extensor, pectineus and sartorius, and the most marked effect will be secondary flexion of the knee joint from the unopposed action of the hamstrings; anesthesia extends over the front of the thigh and along the inner side of the leg and foot as far as the ball of the great toe. (From Rose and Carless' *Surgery.*)

7. *The sphenoidal fissure transmits:* The motor oculi, patheticus, the three branches of the ophthalmic division of the trigeminus, and the abducens nerves, and some filaments from the cavernous plexus of the sympathetic; the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery, and the ophthalmic vein.

8. *The salivary glands* are the two parotid, two sublingual, and two submaxillary glands.

Stenson's duct (from the parotid) opens in the mouth opposite the second upper molar tooth.

Wharton's duct (from the submaxillary) opens on the floor of the mouth at the side of the frenum of the tongue.

The *ducts of Rivinus* (from the sublingual) open on the floor of the mouth near the frenum of the tongue.

9. In passing from the spleen to the under surface of the middle toe, blood passes through: The splenic vein, portal vein, hepatic vein, inferior vena cava, right side of heart, pulmonary artery, pulmonary veins, left side of heart, aorta, common iliac, external iliac, femoral, popliteal, posterior tibial, external plantar, and third and fourth digital arteries.

10. ANKLE JOINT. *Bones*—Tibia, fibula, astragalus. *Ligaments*—Anterior tibiotarsal, posterior tibiotarsal, external lateral, internal lateral.

PHYSIOLOGY.

1. *Arterial pressure* is produced and maintained by: The force and contraction of the left ventricle; the volume of blood pumped by the heart into the already full arteries; the action of the aortic semilunar valves in preventing regurgitation of the blood into the left ventricle when it goes into diastole; the elastic resiliency of the middle coats of the large arteries; the peripheral resistance exerted by the muscular wall of the arterioles, which are especially controlled by the vasomotor nerves; the increased surface over which the blood flows through the capillaries; and the tension of the extravascular tissues. The *capillary pressure* depends upon the condition of the arterioles. If the arterioles to a part dilate, the capillary pressure rises; if they constrict the capillary pressure falls. If, however, the venous pressure is raised, the capillary pressure must consequently rise too. Gravity very materially influences the capillary pressure.

The *venous pressure* is influenced by: The presence of valves, which prevent a backward flow; and respiratory movements. (From Lyle's *Physiology.*)

2. *The alkalinity of the blood may be decreased* during health by (1) great muscular exertion, and (2) by exposure of the blood to conditions of coagulation. Path-

ologically, the alkalinity of the blood may be decreased by (1) anemia, (2) uremia, (3) rheumatism, (4) high fever, (5) diabetes, (6) cholera. (Hall's *Textbook of Physiology.*)

3. *Osmosis:* "If two different liquids are separated from each other by a porous partition, a current sets in from each liquid to the other. The strength of these currents depends on the facility with which the liquids are imbibed by the partition and the tendency the two fluids have to mix with each other; the fluid which soaks most rapidly into the partition—*i.e.*, that which wets it most readily—passes through it most rapidly. If a bladder be filled with syrup and immersed in water, the water will pass into the bladder more rapidly than the syrup passes out, and may so far raise the pressure in the interior of the bladder as to burst it. The water is said to pass into the bladder by endosmosis, and the syrup to pass out by exosmosis. Dialysis differs from osmosis in this: In dialysis a crystalloid in solution passes into a fluid, which contains a smaller quantity of the crystalloid; osmosis occurs at the same time, but the phenomena are quite distinct. The law of osmosis deals only with the currents of liquid. The blood-vessels of the alimentary canal absorb fluids by osmosis. The plasma has only a very slight tendency to pass out of the vessels, while the liquids contained in the alimentary canal pass into the blood with great readiness. The *laws of osmosis* are: (1) The liquids must be of different densities. (2) They must be capable of mixing with each other. (3) The membrane must be permeable to at least one of the liquids. (4) The current produced is greater the greater the tendency of the liquid to permeate the membrane—the greater current is spoken of as endosmosis, the lesser as exosmosis. All these conditions exist between the blood and the fluids with which the blood-vessels are surrounded, and the fluids outside the vessels pass into them more readily than the blood plasma escapes. Endosmosis usually occurs from a lower to a higher pressure."—(*Aids to Physiology.*)

Examples of osmosis in the human economy: "In the body we have aqueous solutions of various substances separated from one another by membranes. Thus we have the endothelial walls of the capillaries separating the blood from the lymph; we have the epithelial walls of the kidney tubules separating the blood and lymph from the urine; we have similar epithelium in all secreting glands; and we have the wall of the alimentary canal separating the digested food from the blood vessels and lacteals."—(Halliburton's *Physiology.*)

4. The secretions of the alimentary canal are: Saliva, gastric juice, pancreatic juice, bile, and succus entericus. Of these the gastric juice has an acid reaction; the others, alkaline.

The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The functions of the gastric juice are: (1) To change proteids into proteoses and peptones, and (2) to curdle the casein of milk.

The functions of the pancreatic juice are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The functions of the succus entericus are: The secretion of enterokinase, secretin, and erepsin, which assist the pancreatic juice in digestion.

SECRETIONS.	ACTIVE PRINCIPLES.	FUNCTIONS.
Salivary	Ptyalin.	Changes starches into dextrin and sugar.
Gastric	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic	Trypsin.	Changes proteids into proteoses and peptones and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal	Invertin.	Converts maltose into glucose.

5. Bile is a secretion of the liver; it contains water and solids. The latter are bile salts (sodium taurocholate and sodium glycocholate), mucin, bile pigments (bilirubin and biliverdin), cholesterin, lecithin, neutral fats, and inorganic salts (NaCl, KCl, and phosphates).

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The bile is secreted in the liver; it passes by the hepatic duct and cystic duct to the gall-bladder, where it is stored; it then passes down the cystic duct, through the common bile duct, and into the duodenum.

6. *Foods are classified:*

- I. Inorganic. { Water. / Salts.
- II. Organic. { Non-nitrogenous. { Carbohydrates. / Fats. / Nitrogenous—Proteids.

Examples of each: *Carbohydrate*, sugar and starches; *Fat*, fat of meat, and butter; *Proteid*, flesh of animals, and white of eggs; *Salt*, sodium chloride, and calcium phosphate.

7. The *functions of the skin* are: (1) Protection, (2) excretion, (3) secretion, (4) regulation of body temperature, (5) absorption, (6) general sensation, (7) special sense of touch, and (8) respiration.

Matters excreted by the skin: Water, salts, urea.

Certain drugs (as pilocarpine) increase the amount of perspiration; others (as atropine) diminish it. The ingestion of much water increases the amount of perspiration. The excretion of much urine causes a diminution in the secretion of sweat; in uremia there is more urea than normal in the perspiration.

8. The *functions of the kidney* are: (1) To secrete (or excrete) urine; (2) to regulate the reaction of the urine; (3) the formation of hippuric acid; (4) regulation of the composition of the blood plasma by excretion of abnormal or toxic substances; and (5) the production of an internal secretion. The mechanism of the *secretion of urine by the kidneys* is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea, and principal solids are eliminated.

"The urine is secreted continuously by the kidneys."

Impairment of the function of the kidneys throws

more work on the skin, which it can only partially perform; some of the work must also be performed by the lungs.

The specific gravity of the urine, in health, may vary from about 1015 to about 1025.

9. *Nerve fibers and nerve cells.* Nerve cells are of different sizes and varying shape; some are ovoid, some irregular in outline. Each cell has a large, distinct, spheroidal nucleus with a single nucleolus and fibrillated protoplasm. Nissl's granules are sometimes found in the protoplasm. From the cells are given off axis cylinder processes or *neuraxes*, and protoplasmic processes or *dendrites*. These are the principal elements in nerve fibers. Every nerve cell has an axis cylinder process, which in the medullated nerve fiber becomes the axis cylinder, and in the non-medullated is the nerve fiber itself. The function of the nerve cell is to receive, or to send out, or to modify, nerve impulses; the function of the nerve fiber is to carry nerve impulses.

NERVE FIBERS.—1. *Medullated Fibers.*—"Medullated nerve fibers usually consist of three parts: (*a*) axis cylinder, (*b*) medullary sheath, (*c*) neurilemma. An *axis cylinder* is a cell process that carries an impulse away from the nerve cell. It is a slender cytoplasmic process and may be very long, as is the case with the motor fibers that come from nerve cells in the anterior horn of the spinal cord and extend, without interruption, to muscles in the distal parts of the limbs. The axis cylinder presents a longitudinal striation, a fibrillar structure, that is supposed to be continuous with the cytoplasmic striation of the cell body. The fibrils are imbedded in a fluid protoplasmic substance, the neuroplasm, and the whole surrounded by a delicate membrane, the exolemma. Implantation cone is an elevation that is sometimes present at the junction of the axis cylinder and cell body. The *medullary sheath* (white sheath of Schwann) is a covering to the axis cylinder. This sheath never extends to the nerve cell, but begins a little distance from it. Nodes of Ranvier are constrictions of this sheath at regular intervals. The smaller the fiber the greater the distance between these nodes. Long fibers are slender, with long distance between the nodes; short fibers are coarse, with short distance between nodes. The *neurilemma* is a thin structureless membrane that surrounds the medullary sheath. An oval nucleus is present in this sheath, midway between the nodes of Ranvier. At each node the neurilemma is constricted and touches the axis cylinder, which in turn may be slightly thickened at this point and may give off a collateral. Medullated nerve fibers with a neurilemma are found in the cranial and spinal nerves. Medullated fibers without a neurilemma are found in the brain and spinal cord. The neurilemma gives great strength to the fibers. Its absence in the brain and cord accounts for the pulpy soft nature of this tissue."

"*Non-medullated nerve fibers* with a neurilemma, but without a medullary sheath, mingle with the medullated fibers. The sympathetic system consists largely of non-medullated fibers. Terminal branched endings of an axis cylinder, called neuropodia, have neither medullary sheath nor neurilemma. The axis cylinder, just as it leaves its nerve cell, is likewise uncovered."—(Hill's *Histology.*)

10. *Reflex actions* are involuntary or unconscious movements due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. *Example:* The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

Illustrations of morbid reflex action can be seen in tetanus, when a slight touch, or even a breath of air, on the skin may cause convulsions of the whole body; also in the vomiting of pregnancy.

CHEMISTRY.

1. *Phosphorus* exists in four forms. The two most common are: *Yellow phosphorus*, a translucent solid which becomes opaque when exposed to light; it is poisonous, of waxy consistency, and when exposed to air it gives off white fumes and an odor of garlic. It ignites readily, is insoluble in water, but soluble in oils, alcohol, ether, and carbon disulphide. *Red phosphorus* has no odor and no taste, is insoluble, not luminous, and not poisonous.

Three compounds of phosphorus.—Phosphoric acid, H_3PO_4. Hydrogen phosphide, PH_3. Phosphorus pentachloride, PCl_5.

2. Silver nitrate solution and salt solution enter into double decomposition, producing sodium nitrate and silver chloride: $AgNO_3 + NaCl = NaNO_3 - AgCl$.

3. Chlorine may be made by heating together hydrochloric acid and manganese dioxide:

$$MnO_2 + 4HCl = MnCl_2 + 2H_2O + Cl_2.$$

Chlorine has a tendency to unite with other elements sometimes violently, with evolution of light and heat. A candle burns in chlorine with a faint flame and thick smoke. In the presence of water chlorine is an active bleaching and disinfecting agent.

4. *Simple proteins* are naturally occurring proteins which on being treated with enzymes or acids break up only into alpha-amino acids or their derivatives. They differ from the (compound or) conjugate proteins in that the latter break up not only into amino-acids, but also into other non-protein substances.

Compound proteins are compounds of simple proteins with some other non-protein group.

5. *Glucose* is a monosaccharide carbohydrate, with the formula $C_6H_{12}O_6$. It is sometimes employed in solution intravenously, because of its nutritive properties.

6. Three hydrocarbons: Methane, CH_4; ethane, C_2H_6; propane, C_3H_8. Three carbohydrates: Glucose, $C_6H_{12}O_6$; saccharose, $C_{12}H_{22}O_{11}$; starch, $C_6H_{10}O_5$.

7. *Fischer's solution* is composed of sodium carbonate, sodium chloride and water. It has been administered intravenously in order to make the urine alkaline.

8. *Test for free hydrochloric acid in gastric contents.*—Gunzburg's reagent (phloroglucin, 2 grams; vanillin, 1 gram; dissolved in 100 cc. of alcohol) freshly prepared, and a few drops of filtered gastric contents (equal parts of each) are mixed in a porcelain dish, and then evaporated in a water bath; in the presence of free mineral acids a bright scarlet color is produced, beginning at the upper border.

The presence of lactic acid is detected by Uffelmann's reagent, which consists of a solution of ferric chloride and phenol, diluted to an amethyst-blue color, which is changed to yellow by lactic acid. In order to avoid error by the action of other substances which have a like action upon the reagent, 10 cc. of the filtered gastric contents are agitated with ether, and the ethereal extract separated and agitated with the reagent; or it may be evaporated, the residue dissolved in water, and the solution added to the reagent.

9. First of all, test for *albumin*, as follows: The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid the urine is simply heated to near the boiling point. If the urine be neutral or alkaline it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

If albumin is present it should be removed. The urine is then tested for *sugar* as follows: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

10. *Chemicals used in purifying water for drinking purposes:* Ozone, chlorinated lime, chlorine, potassium permanganate, alum, sulphate of iron and lime, metallic iron, copper sulphate. For details as to their methods of employment, see Rosenau's *Preventive Medicine.*

MEDICAL WOMEN, YESTERDAY AND TO-DAY.*

BY SARAH J. McNUTT, M.D.,

NEW YORK.

EARLY last year the general public seemed to have suddenly awakened to the fact that the woman doctor was receiving marked attention, and her work was enthusiastically commented upon by press and populace. The clubs, curious to know more in detail, requested information regarding the woman doctor's preparation and experiences.

The very busy life of a woman physician and the ethics of the profession have limited personal reports. After considering the subject and consulting with a number of the leading workers, it was decided that the times required that some concession be made to these requests.

This paper is the outgrowth of my efforts to reply. Your Chairman of Program has asked me to repeat it here.

Sorosis Chairman of Education asked me to tell them if I regretted that I had not a better foundation in medicine. In reply I said I have never for one moment regretted that I was a graduate of the New York Infirmary for Women and Children. Nor do I believe that any other College in the land could have builded for women a better foundation than was there laid for medical work.

It was in 1848 that a plan of studying medicine became a settled resolution with Elizabeth Blackwell. She was the real originator of the idea and movement in America. She was graduated in 1849 and was the first English-speaking woman in the world to take a medical degree.

Her sister, Emily Blackwell, was graduated in medicine three years later, in 1852, and they having realized the needs of a hospital where women and children could receive medical care from women, set about founding the Infirmary or Hospital.

The New York Infirmary for Women and Children was incorporated in 1853 as a center for the *practical* medical education of women. At first it took the form of a hospital and dispensary, and not a college, because there was then no hospital or dispensary open to women students in this country. Many students were from time to time admitted to the infirmary and dispensary for private instruction, and as their number increased it was deemed expedient to establish a woman's medical college in connection with the New York Infirmary and Dispensary.

*Read at a meeting of the Women's New York State Medical Society, Albany, May 20, 1918.

Through the earnest and well-directed efforts of Doctors Elizabeth and Emily Blackwell, a charter was obtained from the State Legislature in 1868 for the establishment of the college, fifteen years after the infirmary and dispensary had been founded.

On Nov. 2, 1868, Dr. Elizabeth Blackwell, in her opening address, said at its close: "The college must be an honest and earnest attempt to give to women the very highest education that modern science will afford." These ideals of Dr. Blackwell in the years that followed were never lost sight of as long as the college lived. It was resolved at the first to make the quality of the instruction and the requirements for graduation equal to the best schools for men in this country. Soon after this college was founded, Dr. Elizabeth Blackwell went to England to live and assisted in founding there the London School of Medicine and the hospital connected with it, developing a great work for medical women; many of its graduates have done most commendable work throughout Great Britain and most wonderful war relief work since 1914 in England, France, and Serbia.

Dr. Marie Zakzrrewska obtained her degree in medicine some years after the New York Infirmary was founded and she was associated for a time with the Drs. Blackwell when she went to Boston, where she founded, in 1862, the second hospital in this country to be staffed by medical women—the New England Hospital for Women and Children in Boston.

These two great centers, Boston and London, were outgrowths of the New York Infirmary.

After Dr. Elizabeth and Dr. Zakzrrewska went to their own fields of medical work, Dr. Emily Blackwell remained alone at the head of the medical work of the New York Infirmary and College for Women. The name of Dr. Emily Blackwell means much to those who have known her personally.

I can never forget the first time that I saw her. When I came to apply for entrance to the college, there came into the reception room a stately woman with white hair, clear complexion, pink cheeks—and, though reserved in manner, yet there was a something about her that made one feel at once that it would be a privilege to be under her teaching and that one must really come up to the standards she set.

I was very fortunate in coming in close relation to her. I lived in the hospital my first student year, and for a year as interne after my graduation. I was her assistant for over twenty years, and also attending physician to the hospital and instructor in the college in her department, diseases of women,

for over twenty years, performing minor and major operations.

While life was simple and an interne's duties varied and laborious, it was fully counterbalanced by the intimate cooperation between internes attending and consulting physicians and trustees.

It fell to an interne to do what is now considered her legitimate work, and also that which is now detailed to hospital druggist and operation-room nurse.

Before the days of isolating wards, equally with other maternity hospitals of the land we sometimes had cases that were then called "childbed fever," and once, with the proverbial Blackwell thoroughness, we decided to fumigate the whole hospital. Patients and workers were transferred to other quarters, windows and doors were sealed, and large quantities of sulphur ignited. Soon the fumes began to extend to the outer air.

It had not been thought sufficiently important to notify the trustees, but it chanced that this special time was selected by Robert Haydock, our beloved president of the hospital board, and Hannah, his wife, whose very presence was always a benediction, to make a friendly evening visit, coming as usual, in their quaint Quaker garb. What was their horror in finding fumes of sulphur escaping and no response to their persistent knocking! Greatly alarmed for the inmates, the neighbors were aroused and the fire company called out.

After it was all over, Dr. Blackwell, who always saw the amusing side, naively suggested that "the next time perhaps it would be well to leave the janitor in the building," but a compromise was made by having him act as watchman on the outside.

No one could fill the place Dr. Blackwell occupied in one's heart. Truly, she was a woman whom it was a privilege to have known and loved. In all the years that I was so closely associated with her, I never knew her to be ill but once. She was out of town at her country place in Orange. I was notified that she was having a very acute gastrointestinal attack, with alarming symptoms. I went at once, and fearing I might need assistance, left word for a younger worker (Dr. Kilham) to follow.

I found Dr. Blackwell alone in her house, unconscious—no pulse at her wrist, heart sounds very weak, with cold extremities and clammy skin. I was busy using restoratives, when the maid returned—she had been at the neighbors reporting Dr. Blackwell's great improvement, because the doctor was so quiet. Dr. Kilham soon arrived and we worked unceasingly during the entire night before we could feel that there was an encouraging response to treatment, and it was well into the morning before she was able to recognize us.

The time was August, the weather specially hot and depressing—she longed for sea air, and as soon as I could do so safely I took her to Nantasket Beach, where we spent our time idling about in most delightful air.

I never shall forget the night on the Sound boat, we could not sleep and sat up in the moonlight and talked, or rather she did, one needs must feel that it was best to listen when she talked—that night is among one of my most precious remembrances.

Dr. Emily Blackwell was a great teacher, and no one could come under her wonderful influence without feeling that a great privilege had been her's. A broad-minded woman, guided by high ideals and lofty purposes, her personality made a strong impress upon the life and work of her students—their lives were fuller from having known her.

The college closed, but it did not die, it never can in the minds of its alumnæ. Its growth was so strong it blossomed and bore fruit, with good seed that has been scattered so far about there must ever be the individual or the group that see the vision, and be ever ready to give themselves to the great service.

This woman's college was the first college to require a three years' course of eight months each year, and among the first to increase the three years to four years.

It was among the first to establish entrance examinations, ten years before such examinations were made compulsory by the State.

When the New York Infirmary issued its first prospectus no college in the United States required so thorough a course or such severe examinations.

The first chair of hygiene was established here, and Dr. Blackwell said "The prevention of disease is quite as important as the cure." She also established the first chair of pathology in this country.

A special board of examiners was selected from among the faculties of the several men's medical schools of the city. When one realizes that this board which examined the candidates, passed by the faculty, and which could refuse them their diplomas, were composed of the leading men in the profession—such men as Stephen Smith, Fordyce Barker, Austin Flint, Alfred Loomis, Gaillard Thomas, William Polk, and Robert F. Weir—the ability of the graduates is unquestioned.

The record of the college was one of steady progress. The well-equipped laboratories allowed the desired extension of the scientific courses, under a corps of thoroughly trained enthusiastic instructors from among our own graduates.

The most distinctive feature of the four years' course was the clinical instruction—it was the keystone of the entire curriculum, toward which everything else was made to converge. The clinical opportunities of a New York medical school for individual instruction in the study of diseases are unequalled by any in the land.

Each senior assisted at twelve maternity cases, under direction of the physician in charge, and made written reports of these cases. This was at the time when men's colleges made no arrangements for their students to see even one maternity case before graduation.

Dr. Blackwell insisted that the student be taught to study the patient as well as the disease, since no two persons having the same disease would show the same symptoms; in each the symptoms would be modified by individual idiosyncrasies.

In our own dispensary at this time—1880—about 8,000 new patients were treated annually; they made from one to many visits—in all there were 40,000 to 50,000 calls yearly.

Not only our own clinics, but the numerous positions held by the faculty of this school in other institutions, were utilized for the benefit of our students. Dr. Blackwell selected the members of

her faculty wisely and well, from the several best male colleges of the city. I give a few names typical of the rest, and indicative of the valuable teaching powers of the school—the two Jacobis—Abraham and Mary Putnam, known and honored on two continents—Abbe, Fox, Dana, Adler, Stimson, Bulkley, Judson, Willy Meyer, Tuttle, Cragin, Chapin, the two Lamberts, Samuel and Alexander. All of these need no introduction or commendation from me.

The alumnæ may well be proud of the fact that their Alma Mater kept up with the times, won the cordial respect of the medical profession and received warm and repeated testimony from the State Board Examiners as to the thorough preparation of the students. It was these superior clinical advantages which brought many students to our senior classes, who had taken their earlier instruction in colleges with less clinical opportunities.

The New York Infirmary College, with its high standards for education, its eminent teachers, could give its student body vastly greater individual opportunities and advantages than could be obtained in a large coeducational institution with many hundred students. Dr. Blackwell believed if women were to study medicine, and expected to be recognized by men physicians, they must be prepared not only as well as men, but even better. However, it had always been Dr. Blackwell's idea that when the best colleges for men opened their doors to women, it was better for women medical students to study at a coeducational medical college, that the world at large would know that they were equally prepared with men.

Cornell Medical College in 1899 received an endowment of $1,500,000, with the proviso that women should be admitted on equal terms with men. The infirmary college was closed, its building transformed into a hospital annex, and its pupils transferred to Cornell. To the general public the broader field seemed a great step in advance for the woman medical student. To the medical woman who knew the wonderful individual teaching and the great amount of practical work to supplement the college lectures, it seemed a tragedy.

I am glad to have been graduated earlier. I had four college years. The first one I lived in the hospital, acting as assistant in the wards, also attended the college lectures, made daily visits in the wards as assistant, recorded patients and their symptoms, carried out directions given for their comfort and treatment. The various wards were, maternity, general medical, general surgery, diseases of children, and diseases of women. Many minor and major operations were performed in which I could assist and do all the dressings necessary during convalescence. I had entire charge of the delivery and made records of 54 maternity cases during my college course, and in addition was present at the delivery of more than double that number, while serving as interne.

Every other morning I worked in the dispensary drug room, making pills and powders and mixtures, even our own tinctures and ointments and suppositories, and filled out the prescriptions given by the dispensary physicians, these prescriptions averaging 100 to 200 daily. The work in the drug room has changed greatly since those days when simpler medicines were used. In place of compressed tablets, bought by the thousand from the wholesale druggist, we had to weigh out and put up bulky packages of "simple bitters," composed of boneset leaves, chamomile flowers, columbo roots and quassia chips. These packages were much prized by our old ladies, who joyfully added the quart of cold water, kept it in the ice box as directed, and cheerfully drank their cupful three times a day, confident that it removed all ills. Loath to part with their beloved remedy until all its virtues were exhausted, they renewed the quart of cold water until there was no longer a bitter taste to the infusion.

When my year of internship was over I was appointed to the out-practice for one year, and visited over 1,500 patients in their homes. Our professors were always ready to help with advice or assistance when needed. I went from sub-cellars to attics, sometimes up seven flights of stairs. I never thought of the stairs, but what they were taking me to, and what I could do when I got there.

Early in the out-practice I realized the great value of the practical work we had had in combination with our college lectures, and how well they had helped to prepare for the emergencies that would arise in active practice.

One of the first calls I received has been ever memorable. I had gone to the dispensary for the addresses for that day's calls. Suddenly a 15-year-old boy rushed in with, "I want a doctor quick—me brother's choking to death—he'll die if you don't hurry." This to me as I'd been pointed out to him as the one he wanted. As he explained, I knew what I was up against, and suddenly in a panic, turning to our anatomy professor, Dr. Wattles Founce, who stood near, with, "Oh, do go! I'll surely cut the carotid artery." She exclaimed indignantly, "If you do, it will be murder, and you will be hung, and you'll deserve it. You know what to do. Get your knife and strip of adhesive plaster, and wind it while you run, don't let him die while you linger in going." She was born in Kansas, but was an ideal New England Priscilla. I knew better than to urge, and did not care to—my panic was gone. The boy ran, I after him, winding the knife. We ran from Eighth Street up Second Avenue to Eleventh Street, east on Eleventh Street three long blocks. If for a moment I lagged he'd call back over his shoulder, "Me brother is a-choking, you know," and on again I'd go. I was at his elbow as we arrived at the house. The door entered directly level with the sidewalk, and the room door was right by the entrance. As the boy threw both open, I saw at once a man on a straw pallet on the floor, sitting up in the corner pressing both arms as high as he could firmly against the wall on each side, to get all air possible into his lungs. His face was black, eyes bulging, and expression agonized. I had not stopped running, and was immediately on my knees at his side, depressed the tongue, saw a great black mass—which was both tonsils greatly distended—filling the passage and obstructing the entrance of air. Passing in the knife, I introduced the point into the black wall and drew it well down on one side. There was an immediate evacuation of contents, with some blood, and he fell forward on his bed, and for an instant

I saw that rope dangling for me, was sure the artery was cut—but only an instant, for my finger was on his pulse and I recognized that the beat was regular and forceful, that his black face was becoming red, as air rushed into his lungs, and his agonized expression was gone—in a few moments he could sit back in the corner while I lanced the other tonsil. The quick change in his appearance was wonderful, and I was glad to have helped to make it so.

During one of these years I received a hurry call from a clinical patient. She feared her child was dying. I found an 18 months old boy gasping for breath with diphtheritic croup. He was lying in bed with his mother, who had been confined a few hours before. The new baby was on the other side of the bed. The locality was in one of the most crowded tenement sections of the city. The door of the living room opened directly upon the street and was even with the sidewalk. Both inside and out it was one of the most unhygienic places I had ever been in—truly not one to select for an operation, but there was no choice, the child could not live more than a few moments if not relieved. Quick tracheotomy made breathing easy. I was giving instructions to physicians, post-graduate students, at this time, at the Morgue upon the operations of children, and the technique of this one was very familiar to me.

On my arrival, and on seeing the existing conditions, I had sent at once for two of the senior students, whom I knew I could rely upon. It was a wonderful opportunity to demonstrate what perfect care could do. These students arrived quickly and were installed. To their untiring vigilance, skillful manipulations, tact, and gentleness in managing the little patient was due its rapid and complete convalescence.

This two-roomed tenement was a comparatively quiet home by day, a well-filled lodging house by night. The lodgers began to arrive by late evening, the door opened noiselessly, by ones or twos they glided in like specters, silently arranged themselves on the floor, seemed to be trying to efface themselves, and the students let them feel that they did. At early dawn they began to glide out as they had come, and soon only the mother and two children were left.

When I arrived early the next morning with two other students to relieve them I found quite normal respiration, and the bright appearance and evident well-being of the patient, made certain his recovery, and their work had made this possible. One Dr. Kilham, after many years of hospital experience here, went "over sea," and for three years has been "somewhere in France," making herself necessary to the people in the devastated sections. The other is my sister, Dr. Julia G. McNutt—most of you know her so well, do I need to add more? While my calls were for medical or surgical attendance, I sometimes encountered on my way to them those that demanded immediate "social service." There was an especially large old dilapidated tenement, recorded as "housing 1,000 souls," that furnished me a large experience, by reason of its very bad sewage and its poor ventilation. It had many inner dark rooms that were only provided by windows and doors opening upon the halls. These halls were lighted by the outer door below, and the closed skylight seven stories above. Sometimes these dark rooms furnished homes for whole families, dependent upon light from kerosene lamps.

Once I was called to a patient on the top floor of this building and I was part way up these stairs, when I saw through an open door a man and woman unconscious on the floor—intoxicated. Strange to say, everything about the room and the individuals was neat, comfortable, and home-like—it seemed a sudden giving up of hope, and an effort to gain oblivion. On the table in the center of the room was a large kerosene lamp burning. The woman had caught the tablecloth as she fell, it was partly wound about her, and was stretched taut. The lamp had been drawn to the very edge of the table. The slightest movement of her body would have instantly tipped it over upon her head and shoulders.

I quickly stepped around and over her, turned out the light, set it back on the mantel out of danger, and continued my way up to the top floor, to my patient, comforted by the thought that I had just prevented a great panic. How many, think you, of those 1,000 souls would have lost their lives in their frantic race down those rickety stairs, struggling with fire and smoke and fear.

When I first entered the medical college I heard a student who had been considering the amount of work that the college required from its students, anxiously ask Dr. Blackwell, "When we have done all this, will patients trust us, and come to us for treatment?" Dr. Blackwell replied, "There are a great many women and children needing good medical and surgical care—if you prepare yourself so well that no one else could do better work, you will soon have so much to do that you will not have time to wonder if some one else does not approve of women physicians." Dr. Blackwell's students found by experience she was right.

For six years I assisted the professor in children's diseases, at the end of that time was asked to take a position on the faculty of the Post-Graduate College, to give clinical lectures in diseases of children three times a week to men and women physicians. One year later, 1883, I founded there the Babies' Wards for Children under 2 years, the first place where such children could be admitted to a hospital without their mothers. I gave bedside instruction and gave instruction in child surgery and autopsies twice a week in the Morgue to these doctors.

There came a time in 1888 when there was the need of withdrawing from some of my hospital and college work. Though greatly interested in my children's work I could not give time to children in my office or see them at their homes—this work had to devolve entirely upon my assistants. My office work was wholly devoted to general and special diseases of women, and the Infirmary work was in that line of practice. Therefore, in 1888 I resigned from the Post-Graduate College and Babies' Ward.

Some of the members of my Auxiliary Board urged that we found a Babies' Hospital. It was thought that I would be able to take the medical care with my sister, Dr. Julia G. McNutt's help, since there would be no college duties that required so much of my time as the work at the Post-Graduate College and Babies' Ward had done.

A charter was obtained from the State Legisla-

ture in 1888 for the establishment of the Babies' Hospital of the City of New York, for children under 2 years. The charter members were: Mrs. Andrew H. Smith, Mrs. Thomas E. Satterthwaite, Mrs. J. Lenox Banks, Dr. Julia G. McNutt, Dr. Sarah J. McNutt. The consulting medical board was selected from among the most eminent specialists of the city. They gave hearty co-operation and support to our work. They were: Dr. Andrew H. Smith, president of the Academy of Medicine, professor of General Medicine at the Post-Graduate College and Hospital; Dr. Thomas E. Satterthwaite, Professor of Heart Diseases, Post-Graduate Hospital and College; Dr. Edward B. Bronson, Professor of Diseases of the Skin, New York Infirmary; Dr. Francis Kinnicutt, Professor of Diseases of Children, Columbia University.

The Babies' Hospital of the City of New York obtained a temporary home, and was opened at 161 East Thirty-sixth Street, June 16, 1888, with 24 beds for patients. At the end of the first six months I made a report of the work, which was read before the Alumnæ Association of the New York Infirmary, February 18, 1889, and was published in the MEDICAL RECORD, March 2, 1889, under the title "The Babies' Hospital—A Summer's Work."

This medical work, however, grew so rapidly, and encroached so much upon our private work, that we felt obliged to withdraw from the Babies' Hospital a year after assisting in founding it. The hospital found a permanent home at Fifty-fifth Street and Lexington Avenue, where it now remains.

Medical Women of To-day.—A definite place in the field of medicine has been won by women. Over 40 coeducational medical colleges in the United States admit women on the same terms as men—Columbia University in 1916, and Harvard, 1917, and Yale has announced that she will admit women this fall, 1918.

The opportunities for women in medicine were never so numerous or so remunerative as at the present time, both here and abroad. No occupation open to women is so signally attractive from every point of view. It offers practically an unlimited field for usefulness and financial success. The influence of the woman physician increases, rather than diminishes, as she grows older, an advantage peculiar to medical practice. The demand for women physicians exceeds the supply. Of what other profession or occupation open to women can that be said? The woman physician is sought, not only as a private practitioner, but also as a salaried officer in institutions, medical and otherwise, as an expert in sanitation, care of the feebleminded, and treatment of the insane.

New needs for the women physicians are springing up every day, and not enough women are entering the profession to profit by the constantly increasing opportunities.

War Relief.—Of the more than 6,000 women physicians in the United States, over 2,200 have registered to be ready "at call" for war relief—over 30 per cent. of all the medical women graduates of the United States.

A goodly number have already braved the submarine peril and landed "somewhere in France," giving up home and practice, willing to face hardship and peril, without the help of military glory, to bring comfort and succor to the stricken people of that devastated land.

Truly they are worthy followers of our great pioneer and teacher, Dr. Emily Blackwell.

265 LEXINGTON AVENUE.

PROTEIN TREATMENT OF ARTHRITIS.

BY S. P. BEEBE, PH.D., M.D.,

NEW YORK.

MANY physicians have made the casual observation that a case of chronic arthritis is at times benefited by severe constitutional disturbances that accompany an acute infection, such as typhoid fever for example, and without a satisfactory basis for the deduction other than the observed beneficial effects that have been known to follow such procedures, a variety of therapeutic agents have been given to these chronic sufferers, such as bacterial vaccines of various sorts, including Shaefer's vaccine. A variety of different types of ductless gland preparations have been administered in the form of tablets by mouth as well as extracts given hypodermically. Meanwhile studies on the pathology of these conditions have led us to look for the source of infection in some other part of the body than the joint itself, the toxins from which give origin to the joint reactions. The teeth, tonsils, nasal sinuses, gall-bladder, and appendix very frequently indeed are subject to chronic infections, the toxins from which may give rise to the joint condition. Abnormal conditions within the digestive tract giving rise to absorption of toxic products, and putrefaction therein may likewise prove to be the point of origin of the joint inflammation. It seems unnecessary to state that any plan of treatment designed to relieve the joint condition must take into account these chronic infections, and insofar as it is possible to do so adequate relief must be accorded by medical or surgical means from these disturbances to the general health.

Within the last two years attention* has again been called to the beneficial effects in joint conditions that often follow the administration of the bacterial vaccines of a non-specific type. The general disturbance which follows their administration is accompanied not infrequently by relief in the inflammatory condition in the joint itself. Such a plan of treatment has been in use, as a matter of fact, for many years and it seems probable that the vaccines that may have been recovered from infected teeth or tonsils act quite as much as non-specific agents as they act in a specific manner by combating the infection supposed to give rise to the toxic inflammation in the joint. However, as a matter of practical therapeutics, the attention of physicians has been called very sharply to the method by the work of Jobling, Miller, Thomas, and associates, who have for the most part used intravenous injections of typhoid vaccine as a therapeutic agent. A vast majority of bacterial vaccines, given intravenously, produce a reaction which in severity depends upon the dosage and personal idiosyncrasy of the patient but is accompanied by chill,

*Nearly all the literature on the recent phases of this subject is summarized in Miller's article on the Nonspecific Character of Vaccine Therapy.—*Journal A. M. A.*, Sept. 8, 1917.

fever, leucocytosis, depressed blood pressure, and an occasional collapse. This is the kind of reaction that has been depended upon for many years by some physicians to afford relief from a variety of conditions after the administration of Shaefer vaccines, known by the name of phylacogen, and by Coley's toxins.

Other forms of foreign protein stimulate reaction quite as well as the bacterial toxins, but in most cases a larger amount of the foreign protein must be administered, as bacterial vaccines are quite toxic to a subject by this method of administration. Non-bacterial proteins do indeed vary somewhat in their toxicity, and some may be administered with very little or no reaction, and yet be followed by clinical relief in the joint conditions. The non-specific character of vaccine therapy, and the recognition of the fact that other proteins than bacterial proteins may be suitable for therapeutic uses were the basis for the publication by Jobling, and were the subject of his lecture before the Harvey Society, and while it is possible to measure temperature, blood pressure, make blood counts, and in this way arrive at some conclusion as to the disturbances produced when foreign proteins are administered, Jobling frankly recognizes that all these measurable factors do not adequately explain the therapeutic benefit observed to follow their administration, "but here as in so many other biological problems which have to do with that most complex of tissues, the blood, it seems probable that no single factor can be identified as responsible for all the changes which occur, but that a whole train of events is inaugurated, when the equilibrium of some of the delicate serum balances is disturbed, all of which tend toward a condition favorable for recovery from infection."

The writer has watched the growing sentiment toward protein therapy with unusual interest because during the last three and a half years he has given much time and effort in this direction, and has treated quite a variety of conditions with injections of foreign protein with a resulting therapeutic benefit that has not been observed to follow other lines of treatment. Quite a variety of different proteins have been used in this line of work, prepared by somewhat different methods, practically all having their origin in plants or seeds, but in the MEDICAL RECORD for July 21, 1917, he described a method for preparing proteins from alfalfa and millet seeds which for purpose of non-specific protein therapy have none of the disadvantages which earlier preparations showed and which are simple of administration from every standpoint. A considerable number of patients suffering from rheumatoid arthritis have been treated by the injection of these proteins and the relief experienced by the patients and the constitutional benefits which followed the administration of protein were so decided that in his opinion these seed proteins present all the therapeutic advantages found in the non-specific bacterial vaccines without the admitted disadvantages which the latter show.

Bacterial proteins for the most part are highly toxic when given intravenously in the human subject, and it is a question indeed whether the profound reaction which they occasion is altogether of benefit to an individual already below par from long continued depressing illness such as rheumatoid arthritis often proves itself to be. Miller recognizes these dangers but states that he has treated 200 cases without any grave consequences except one case, an alcoholic, where delirium tremens developed and death supervened 52 hours after the injection. The severe chill, with nausea and headache, high fever, herpes, with a marked fall in blood pressure following the chill, is not an experience to which a chronic invalid should be repeatedly exposed and unless it can be shown, as Miller believes, that the severe reaction is essential to relief, there is no reasonable justification for producing it. Scully, who has been working with Miller, describes in detail the type of reaction observed and notes that the average dose in some instances, especially in those cases in which the patients were bedridden for some time, proved to be excessive and in these cases there was occasioned a severe rigor lasting for one to two hours, accompanied by marked cyanosis, rapid, weak pulse, and following the chill the patient was very weak and showed signs of collapse. He observes "Intravenous injection of vaccine are contraindicated in those cases in which the vasomotor system is weakened and when the nervous system is unstable. In these cases collapse may occur, with the possibility of death resulting. In serious organic heart lesions the injection is seriously contraindicated as the heart becomes dilated and overworked so that cardiac failure may result." While Scully's paper is devoted to the reaction which occurs after the intravenous injection of foreign protein, it should be noted that the foreign protein in all these cases was typhoid vaccine administered intravenously.

Unless it can be demonstrated that these severe reactions are a necessary part of the process by which relief is afforded, there is every reason to avoid producing it. Miller frankly believes that the reaction is essential. In closing the discussion on his paper he states that he has used pollen protein on some of his cases but had some difficulty in getting the right dosage to bring about a chill but when the chill was obtained he got the same results as in the other proteins although he admits that certain German investigators have reported benefit from the intramuscular injection of milk which produced a very mild reaction.

Any foreign protein introduced parenterally stimulates a response on the part of the organism but this response need not be accompanied in all cases by chill and fever, unless the dose introduced is of considerable magnitude. Proteins are not equally toxic by this method of administration. The common method for measuring protein content is the nitrogen determination and if equal quantities of nitrogen are used, certain proteins, such as those found in bacteria, are more toxic to the human organism and will produce severe reactionary responses of a toxic character which are not at all produced when equal quantities of nitrogen expressed in certain seed proteins are given in the same manner. The therapeutic application of typhoid vaccine to this purpose seems hardly better suited than the use of Coley's fluid or phylacogen. The repeated administration of the bacterial proteins with the accompanying chill or fever is not a proceeding which can be repeated with impunity

many times in any patient, and while following the chill and fever there has been noted relief from pain, this admittedly has been of a somewhat temporary character in many instances. The patient must be in a hospital with facilities to afford the necessary care during the reactionary period. Moreover, it has not been shown that the general constitutional condition of the patient is much benefited by the severe disturbances to which he is subjected if bacterial proteins are given in sufficient dose.

The therapeutic agents employed by the writer, as has been stated previously, are the proteins prepared from millet and alfalfa seeds by the process fully described in the article referred to, but the method is essentially one of partial hydrolysis, resulting in the formation of proteins readily sterilized by head without coagulation. The proteins which have been used are in a 2 per cent. solution. They have been given subcutaneously. It is quite possible to produce a reaction of the general character shown by the bacterial proteins if too large a dose is given as a first injection. In the writer's experience it has not been necessary to produce such reactions to get relief. Patients vary somewhat in their susceptibility to these proteins as they do to all proteins. A beginning dose of 10 to 12 minims practically never produces a reaction of the type described. It may be and often is followed by quite as much relief from pain as is the case when the more toxic proteins are administered.

Miller has for the most part been dealing with conditions of acute arthritis which in its pathology is somewhat different from the chronic conditions which may follow the acute infections and which for the most part have been found more difficult to control.

The writer's experience has been almost entirely with chronic arthritis. In the cases, however, there have been three patients with acute arthritis whose joint pain was not controlled promptly by salicylates. In two of these cases the protein injection was accompanied by a mild increase of temperature but without chill and with complete relief from pain. The injections in these two cases were continued for a period of two weeks. There was, however, no return of the pain and the patients made a prompt recovery. In the third case a larger dose, 15 minims, was given for the first injection and in this patient there was a distinct chill with fever following. No further injections were given and none was necessary. As stated, the majority of the patients had chronic arthitis. In some instances it had continued over a period of years. They had been treated by a variety of means including the administration of bacterial vaccines prepared from teeth, tonsils, etc. They were suffering from the depressed physical condition which goes with a long period of toxemia. Many indeed were cripples and bedridden. The injections have been continued over a period of months and the results which have been obtained have been so gratifying as to make it seem probable that this therapeutic method is one of considerable importance in this group of patients. It must be obvious that only in exceptional cases would a patient submit to the administration of vaccine injections of sufficient magnitude to produce chill and fever every second day over a period of some months, and it is in every way probable that such treatment of a chronic arthritic patient would seriously injure rather than improve him. On the other hand these seed proteins have been injected three times weekly in gradually increasing doses over a period covering 4 to 10 months, with the result that the general health has been much improved, painful joints entirely relieved, and the patient restored from a condition of invalidism to one of useful activity. The seed proteins stimulate the blood-forming organs and the patients who have been treated have shown marked improvement in blood conditions. They cause no disturbance to the patient. It is not necessary to be in a hospital or under the constant observation of a nurse, nor do the injections in any way inconvenience the patient or prevent him from activity which he could readily indulge in if no treatment were given.

The writer's experience with acute arthritis is not sufficiently extensive as yet to permit a decision as to what percentage of cases can respond as favorably as the three quoted. In the chronic cases of arthritis approximately 60 per cent. have responded so favorably as to be practically entirely relieved. Chronic arthritis is a more difficult problem to solve than acute arthritis, and a 60 per cent. relief is no insignificant result, particularly when it is obtained by a process that does not inconvenience the patient nor cause any discomfort.

417 Park Avenue.

HAYFEVER POLLEN EXTRACTS AND THEIR STANDARDIZATION.

By WILLIAM SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS.

PRESIDENT, AMERICAN HAYFEVER PREVENTION ASSOCIATION; EX-PRESIDENT, AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY; CHIEF, HAYFEVER CLINIC, CHARITY HOSPITAL.

As the scientific application of pollen therapy is effective in the treating of hayfever,' we have made a careful investigation of the various pollen extracts on the market, with a view of facilitating their application in the treatment and diagnosis of hayfever. As a result of this, we have made certain rules for the standardization of the pollen extracts, which we believe will be advantageous to both the practitioner and the pharmaceutical houses.

The strength of the pollen extracts should be stated in units to the cubic centimeter, the standard unit in pollen therapy being 0.001 mg. of pollen protein. The most convenient strength is 100 units to the c.c., this being the most practical for both the diagnostic tests and the treatment. For the former, we inject into (not under) the skin 0.05 c.c. of this strength, containing 5 units, which is sufficient to produce a well-defined reaction in sensitive subjects, and without danger of developing anaphylactic disturbances.

The usual doses of pollen extracts range from 5 to 50 units, which is represented by 0.05 to 0.50 c.c. of this extract. The pollen extract of 100 units to the c.c. therefore simplifies the application of pollen therapy and diagnosis.

Diluents have been recommended when less than 1.00 c.c. is injected, but we have not found this

necessary or advisable, and, as it unnecessarily complicates the technique, it should be omitted.

The pollen used for preparing a special extract should belong to a single variety or class. Combinations, except as far as they belong to the same class of pollens, should not be used. Our investigations have shown that there are certain pollens in which the biological reactions (hayfever) are similar and which can therefore be combined in one preparation.[2]

In the grasses, for instance, there are about 5000 varieties, and if it were necessary to prepare a special extract for each, this form of pollen therapy would evidently be hopeless. Fortunately, however, the biological reactions for these, while differing somewhat in degree, are otherwise identical.

It is therefore permissible to use any convenient variety of grass pollen, or a combination of several, for the grass pollens. This group is preferably called (1) "Gramineæ," as it includes rye, wheat and other varieties which are not popularly recognized as belonging to the grass family.

In the same manner we have segregated three other groups for their biological reactions, viz.,

2. "*Ambrosiaceæ*." These are the principal causes of autumnal hayfever east of Kansas, and include the common, giant, and other ragweeds (*Ambrosias*), the "false ragweeds" (*Gaertnerias*), the marsh-elders (*Ivas*), and the cockle burrs (*Xanthium*).

3. "*Artemisia*." This group is an important cause of hayfever in the Rocky Mountain and Pacific States.[3] It contains numerous varieties, the most common being the following: Mugwort (*Artemisia heterophylla*), wormwoods sage (*A. frigida*), sagebrush (*A. tridentata*), absinth wormwood (*A. absinthium*), dark-leaved mugwort (*A. ludoviciana*), biennial wormwood (*A. biennis*), California old man (*A. californica*), Indian hair tonic (*A. dracunculoides*), and bud-brush (*A. spinescens*).

4. "*Chenopodiaceæ*." In this group we include the amaranths, chenopods, Russian thistle (Salsola), and docks (Rumex), which, while not botanically as closely allied as the other groups, give a similar biological (hayfever) reaction.

These four groups are responsible for most of the hayfever in the United States. There are some forms of hayfever, such as are due to the cedars, black walnut, and other trees and plants, which are not included in these groups. Most of these cases, however, have a limited distribution, and their pollen extracts, when required, should be prepared especially.

The terms "spring pollen" and "autumn pollen" extracts should be omitted from the manufactured preparations. The autumn hayfever, for instance, in the East, is due principally to the ragweeds (Ambrosias), but in the Pacific and Rocky Mountain States to the wormwoods (Artemisias).

We have a "spring" hayfever in the Gulf States also, which is due to the oaks and cottonwoods, and one in Texas due to the cedars.[4] The extracts should, therefore, be named simply from the contained pollen.

Combined extracts of so-called "spring" and "fall" pollens are not advisable. While our experience of the past two years has shown that susceptibility to both forms is much larger than is generally supposed (42 per cent of cases in Series C), the degree of susceptibility to both varies greatly. Exposure to the grass pollen is usual in the spring, and to the ragweeds (Eastern and Southern States) in the fall, so that both extracts are not indicated at the same time. The principal reason for such a combination being used is to avoid the necessity of making a diagnostic test, which, however, is an essential factor in the success of this method.

The date of manufacture of pollen extracts should be stated. In spite of the utmost care in their preparation, the activity of some of the pollen extracts diminishes materially after the first season. This is observed not only in the diagnostic tests but also in the effects of the treatment.

The use of these rules not only simplifies the application of pollen therapy, but also enables the results to be analyzed with a view of perfecting this method. The manufacturers generally have shown a disposition to cooperate in this standardization of pollen extracts, which will simplify the treatment of hayfever and hayfever asthma.

AUDUBON BUILDING.

A CONSIDERATION OF SOME OF THE PROBLEMS OF HEREDITARY SYPHILIS.*

BY WALTER S. REYNOLDS, M.D.

NEW YORK

QUESTIONS relating to the transmissibility of syphilis by inheritance are of the utmost importance, involving as they do the life, health, and happiness of countless individuals. The physician who is more actively engaged in the treatment of syphilis and has the opportunity of seeing day after day a large number of these unfortunates is perhaps more impressed with the truth of this statement than physicians engaged in other lines of medical work. But in whatever branch of medicine the physician may be interested he is undoubtedly frequently confronted with hereditary syphilis as having a possible influence or being a direct cause of the trouble for which he may be consulted. In our asylums and public institutions many of the inmates bear testimony to the havoc it has wrought in the lives of these pitiable individuals.

While some progress has undoubtedly been made in our knowledge regarding hereditary syphilis, there are still many problems which remain to be solved in this very complex question. Based on clinical evidence alone, as they were, some of our former theories relating to the question have not been found to hold good and it has been found neces-

* Read at the meeting of The West End Medical Society, New York, April 27, 1918.

sary to revise some of our conceptions when we have come to apply more recent methods of investigation to the solution of these problems. The Wassermann test of the blood has shed new light upon many of the obscurities with which the subject was surrounded, and, it must be confessed, in some instances has added new factors to complicate it. While the Wassermann test has its limitations and is not infallible, it undoubtedly affords at the present time one of our most valuable means of determining whether the individual has at some time been infected with syphilis. It is coming to be believed, I think, that further than this we can make no positive statements regarding the value of the Wassermann test. It will probably be some time and require much more extended observation to make definite statements as to its value as an aid in prognosis or as a guide to treatment.

Since the Wassermann test has come into general use as a diagnostic aid in syphilis, greater interest has been taken in the family history of the syphilitic individual. Great assistance along these lines has been given by the social workers who in the past few years have been attached to many of our hospitals and dispensaries. With their aid we have been able to come into closer touch with the families of those who apply for treatment and to investigate many cases in a way that would otherwise be almost impossible.

By a brief review of some case histories we may perhaps be best able to bring out some of the problems which confront us in considering hereditary syphilis.

Case I.—Mrs. D., aged 19 years, came to the New York Hospital in July, 1917, giving the following history: She had been well previous to her marriage in 1914. In 1916 her husband was a patient in Bellevue Hospital. She says he had "boils on the privates," and received one injection of 606. Her first child was born in 1915 and is alive and healthy now. One week after her husband was discharged from Bellevue, Mrs. D. entered the same hospital and remained there for two weeks with "an eruption on the privates." No salvarsan was given, as it was said she was "too weak." A specimen of blood was taken but she is unable to say what the report was. She comes to the hospital with her second child, a girl, five weeks old. The baby is fairly well nourished, being breast fed, but is suffering from snuffles and a marked onychia of both hands and feet.

This woman was undoubtedly infected subsequent to the birth of her first child and had probably been syphilitic for about a year before the second child was born. The mother had no manifest symptoms of syphilis except a general adenitis and a four plus Wassermann. The mother was treated with salvarsan and mercury, and the baby with mercury by inunction. After several months they discontinued coming for treatment and the nurse reported on visiting their home that she was probably prevented from attending by the husband, who resented having her call. The people were dreadfully poor and, of course, ignorant, and the question involved in the case is not one of treatment but the fate of the first child, who is probably sooner or later bound to be infected if allowed to remain in the home, and whether such individuals should be allowed to continue to bring into the world a line of syphilitic progeny.

Case II.—Mr. O., 34 years old, referred to me in May, 1917. In April, 1917, two ulcerated patches developed on the soft palate, one of which had resulted in a perforation. He had been treated for a short time by applications of silver nitrate and a specimen of the blood had shown a four plus Wassermann. Under the use of salvarsan, mercury, and iodides the perforation closed and no further symptoms developed. The man denied ever having had any primary or secondary symptoms and was greatly astonished when told the trouble was due to syphilis. In 1902, a pimple appeared on the forehead over the left eye and was opened several times and treated in various ways but never entirely healed. In 1904, 1906, and 1907 it was excised, and in 1908 was treated by *x*-ray for several weeks. In 1910 it broke down again and a more extensive operation was undertaken for its removal. At this time three specimens were examined and all pronounced by competent pathologists as epithelioma. For three weeks after the operation he was treated by *x*-ray. Healing took place and since that time there has been no recurrence of the trouble. A large scar shows where the lesion was situated, otherwise there is no evidence of abnormality. Mr. O had been married two years and his wife being two months advanced in her first pregnancy and both being most desirous of having a child, he wished to know what the probability was of the child being infected. An examination of his wife's blood on two different occasions showed it to be negative, and clinically she gave no signs of infection. I did not wish to assume the responsibility of making too positive statements and tried to place the matter before him in all its aspects, leaving the decision to him. After getting the advice of several other physicians, they decided to have the pregnancy terminated.

Mr. O.'s Wassermann, in spite of the vigorous treatment with salvarsan, mercury by inunction and by intramuscular injections, and iodide of potassium, still remained four plus until mixed treatment was substituted, when, in a short time, the Wassermann was reported doubtful, and subsequently became negative on continuing the use of this treatment. After the administration of one dose of 0.4 salvarsan, the Wassermann again became positive. The lesion in the mouth, nine months after treatment was begun, remains closed, a depressed scar being the only evidence remaining.

Several features of this case might well be considered in more detail were it not for the fact that this paper has to do more particularly with questions relating to hereditary transmission of syphilis. There are two points, however, to which I should like to call attention.

In our enthusiasm for newer remedies we are not infrequently apt to neglect the older ones which by long usage have shown their value, and I believe this is so to a large extent with iodide of potassium. A striking example of the benefit to be obtained by the use of iodides in such cases was the rapid improvement which took place as soon as its use was begun. The other point to which I wish to call attention was the change in the Wassermann produced by the use of mixed treatment.

In this case the patient was undoubtedly suffering from a tertiary lesion. His denial of all knowledge of primary or secondary manifestations may be questioned by some, but I have no hesitation in accepting his statement. It is not at all infrequent that we find a positive Wassermann with no history of either primary or secondary symptoms. While some of these people possibly are anxious to deceive the physician, in many instances their statements cannot be doubted. As the nature of the lesion was manifest in Mr. O.'s case and there was no evidence whatsoever to show that his wife had been infected, I did not feel that there was any likelihood of the child being syphilitic, yet I did not deem it right to urge too strongly against terminating the pregnancy while believing that all cases of hereditary

syphilis are transmitted through the infection of the mother. I am also of the conviction that in true tertiary syphilis the possibility of infection is not great. The former statement, while contrary to older teachings, is, I believe, warranted by recent investigation, while the views regarding tertiary syphilis also held by many older writers receive additional confirmation.

Case III.—M. B., 26 years old, was brought to the New York Hospital in the ambulance in a comatose condition, Oct. 1, 1917. She remained in the wards for five weeks, during which time she had convulsive seizures at frequent intervals. These would begin as twitchings of the left side of the mouth, extending to the left arm. Under treatment with arsenobenzol, both intravenously and intraspinously, she gradually recovered consciousness and the convulsive seizures stopped. On Nov. 14, 1917, she entered the out patient department as a patient, giving the following history: In January, 1917, on account of severe headaches, she had consulted a physician. He secured a specimen of blood which on examination showed a four plus Wassermann. She received weekly injections of mercury until Oct. 1, when, while on the street, she suddenly became unconscious and was removed to the hospital as stated. The young woman was accompanied by her mother, who gave the additional information in regard to her daughter's infection: Fifteen years previously, the mother had taken as a boarder a child of five months and had kept him until he was seven years old. She stated that he was at the present time in an institution and she had reason to believe that he was the source of infection. To confirm her statement, I visited the institution and was informed that the child was there as she had stated. He was suffering from keratitis, being nearly blind when he entered as well as having lost his hearing. The blood had been examined several times and on each examination had given a four plus Wassermann. Specimens of blood from the young woman taken while in the ward had given a four plus. A specimen of the mother's blood taken on her visit to the clinic gave a negative Wassermann.

The history of these three cases will serve to show some of the problems of hereditary syphilis which we may be at any time asked to answer. In Case I, either the termination of pregnancy or a syphilitic child could be the only possible answer to a woman so recently infected. That the infection may continue to exert its influence for a long period of time will be shown later, and, on the other hand, it seems evident that a four plus Wassermann does not of necessity indicate that the child may be syphilitic. How then are we to decide the question, for a Wassermann certainly does not help us in solving the problem?

As has been said, a surprisingly large number of men and women presenting undoubted manifestations of late syphilis deny having had any primary or secondary symptoms. Leaving out of consideration those who willfully seek to hide their infection, there are no doubt a large number who are perfectly truthful in their statements. The initial lesion may be seemingly insignificant, and the patient gives it little thought. In women, genital lesions are not infrequently so situated as to escape observation. It is a well known clinical fact that a secondary rash has been unnoticed until attention is called to it by the physician, and even without treatment in some cases it may quickly fade. It has been proposed that all persons before marriage should be serologically examined and obtain certificates of freedom from contagious disease. Can we say that at the present time the Wassermann test is an indication of their infectiousness?

In Case II, there being no evidence that Mrs. O. had been infected, the question arises, is it possible for a man suffering from the disease to infect the ovum, the woman remaining free from all signs of the disease? Finger and Landsteiner were successful in infecting monkeys with the spermatic fluid, but it does not necessarily follow that the spermatozoa are capable of carrying into the ovum the infectious organism, a necessity, of course, if we are to acknowledge that this mode of contagion is possible.

In Case III, while we cannot be absolutely sure how the young woman was infected, it seems reasonable to assume that it occurred in the way described. The danger of infection from the hereditary syphilitic infant is well recognized. Unfortunately, the symptoms are sometimes slow to manifest themselves, and such a child as a boarder, especially where there are a number of other children, is a grave danger.

That the children may apparently escape infection where the mother is serologically syphilitic is shown by the following case:

Case IV.—Mrs. Q., a widow, 35 years of age, denies all manifestations of syphilis. She was married ten years ago, and has three children, six, four and two years old. Her husband is said to have suffered from cerebrospinal syphilis. He died in December, 1915, and in January of the following year the blood of Mrs. Q. and of her children was examined. The mother's was positive, while all the children's was negative. Mrs. Q. has been under treatment since that time, and in spite of the fact that she has had several courses of mercury and salvarsan she still has a four plus Wassermann.

In this case we are unable to fix the time when the woman was infected. If it was some time previous to her marriage, the apparent escape of the children from infection would not seem so wonderful. If, however, she was infected by her husband, who was said to have had cerebrospinal syphilis, it hardly seems credible that they could have escaped. It is true that we have here again to consider the value of a negative Wassermann, but I do not believe, in view of the fact that the children have no clinical manifestations, that we should stigmatize them as syphilitic. Did the woman ever have syphilis? If we can place any reliance in our Wassermann test, we must unquestionably answer, yes. It is but fair to state that some observers are beginning to doubt the reliability of this means of diagnosing syphilis. Another explanation, perhaps worthy of some consideration, is that the woman had an abortive syphilis. The persistence and its influence on heredity is so well shown by a case reported by the late Dr. R. W. Taylor in the *N. Y. Medical Journal*, Oct. 19, 1907, that I shall offer a brief summary. It is as follows:

In 1869 a man came under Dr. Taylor's care with primary and secondary manifestations of syphilis. He lived to be fifty-two, and died of aortitis and nephritis. In 1866 he married and his wife subsequently gave birth to eleven children. She became pregnant twice before becoming infected in the third month of her third pregnancy. She was careless of treatment and the second child (the first pregnancy resulted in a traumatic miscarriage) in the fourth month had a roseola, mucous patches, and later other manifestations of syphilis. This child died of croup when four years old. The first child became infected when four years old. The following two pregnancies resulted in still births and evidently syphilitic. Another child, a girl,

apparently healthy when born, died at the age of two and a half years old of gastroenteritis. The mother had taken treatment sparingly and intermittently during this time and suffered from occasional manifestations. Another child, a boy, was born two years later and presented no signs of syphilis until his thirtieth year, when he developed signs of gummatous osteomyelitis. He had not been infected with acquired syphilis at any time. This man married and the wife and one child, five years old, seemed perfectly healthy. Subsequently the woman gave birth to four boys and one girl, the mother neglecting treatment except when she thought herself pregnant. The three boys showed no signs of syphilis, but the girl, who was the youngest, developed osteoperiostitic lesions when sixteen years old.

In concluding his article, among other things, Dr. Taylor drew attention to the following: The seeming benignancy of syphilis in the father and its malignancy and inveteracy in the mother. The evident effect of treatment of the mother upon gestation. The development in one case at the age of thirty of classical hereditary lesions without antecedent manifestations after years of apparent health. And by way of final comment he says: "In the light of the histories herewith unfolded, a serious question presents itself, namely: What will be the fate of the survivors who seem to be in robust health and have never shown a blemish, and what will be the ultimate condition of their progeny? Time and scientific observations alone will answer these queries." Some of the problems involved in a consideration of hereditary syphilis I have tried to bring out in the cases here recorded. The frequency with which it is encountered and its seriousness render it a worthy field for much study and investigation which will help to give us a clearer understanding of some of these obscurities. To prevent the ravages of the disease entirely we must be in possession of all the facts regarding it. Fortunately, much may be accomplished in the way of prevention by thorough and intensive treatment of our syphilitic patients.

In closing, I would ask your consideration of the following: It is well recognized that the hereditary syphilitic child is a grave menace to those with whom it may come in contact. Does it in the course of time cease to be a danger; if so, when, and how are we to determine when it does?

What are our obligations where there are other children in the family who have not been infected? Are we to allow the continued propagation of syphilitic children?

Shall we allow a woman, clinically and serologically free from disease, whose husband is syphilitic, to bear children?

Recognizing that hereditary syphilis may remain latent for many years, is it not our duty to assure ourselves, where there is the least suspicion of syphilis, that the child is serologically as well as clinically free from disease?

It being shown in many instances that a woman with a positive Wassermann may bear children clinically and serologically free from syphilis, what must be our attitude in regard to the Wassermann test so far as marriage and childbearing are concerned?

I wish to acknowledge my obligation to Dr. Fielding Taylor for placing at my disposal clinical material in the Department of Syphilology of the New York Hospital for some of the cases reported here.

132 West 73d Street.

THE RELATION OF THE PROTEINS IN FOOD TO THE CAUSE OF DISEASE.

By ROBERT CURTIS BROWN, M.D., Major M. R. C.

MILWAUKEE, WIS.

SINCE the time of Virchow the attention of physicians has been devoted to the study of the local pathology of disease. But the local pathology is not the cause of disease, though it explains the symptoms; the study of etiology is even more important than the study of pathology, for only by the study of the cause of disease can we have any hope of disease prevention.

In this paper the main object in emphasizing this new factor in the cause of disease is the firm conviction that when this cause of disease is fully recognized, not alone will much unnecessary suffering be alleviated but a great step forward will be taken in the prevention of disease. I do not wish to minimize infection as a cause of disease but merely to show that there is another important cause of disease.

I hesitate to present this paper without quoting the wealth of literature which bears upon the subject or presenting some of the hundreds of cases which illustrate its various contentions. It is a subject upon which volumes could be written and I merely wish in this outline to present the idea as briefly and concisely as possible. When the idea is grasped any physician will recall scores of illustrative cases in his own practice and he surely will be rewarded, if he adopts the principles outlined in the treatment of his cases.

1. Though the origin of infectious disease is well understood the fact that the fundamental cause is the toxic protein constituent of bacteria is not appreciated. This toxic element can be extracted and used to sensitize and kill animals and it will produce symptoms of poisoning when injected into the human body.

2. There is no difference in the toxicity of the protein elements of pathogenic and non-pathogenic bacteria when they are extracted. This shows that pathogenicity does not depend upon the presence of a poisonous toxin at all but upon some other cause in which the resistance of the host plays a part.

3. The fact that all animal and vegetable proteins contain poisonous elements has been abundantly proved. Toxins can be extracted from any of the protein of food stuffs whether animal or vegetable. These toxins are potent to sensitize and kill animals and are poisonous if injected into the human body.

4. That certain proteins are foods does not prove that they do not contain poisonous elements. Protein foods do not normally poison human beings because the mechanism of metabolism, if uninjured, is able chemically to break down the complex protein substances into simpler bodies and build them up again into the complex cellular elements of the tissues in such a way that the poisonous elements are either not liberated, or are so neutralized as not to be able to produce reactions beyond the normal.

5. The protein of each different animal and plant is specific for that animal or plant and differs from that of every other animal or plant in the chemical arrangement of its molecules.

Upon this same chemical arrangement of protein molecules in the tissue cells, depends the ability of the tissue cells to metabolize foreign protein. The arrangement of molecules may be assumed to vary somewhat in the individual, more in the family, and most in the species.

6. For some reason, probably by long continued excess of protein intake, especially animal protein, beyond the amount necessary to maintain a nitrogenous balance and yet keep the body in good physical condition, the human body has overtaxed and injured its apparatus of metabolism, so that it cannot metabolize the protein without undue reaction from the poisonous elements contained in it.

7. I call the symptoms which are produced when undue reactions are caused by the protein of food "protein poison manifestations." These manifestations may take place in any tissue or organ in the body, and the symptoms produced do not depend upon the variety of protein, but upon the tissue in which the manifestation takes place. When manifestations take place in several tissues of the body at the same time we call the protein manifestations "syndromes."

8. There are a large number of diseases and symptoms which evidently are not due to infection. The origin of these diseases has been considered unknown or uncertain and various theories have been advanced to account for their causation. I believe a large majority of these affections are due to the poison element in the protein of food stuffs.

9. While I believe the protein poison manifestations are caused mainly by the protein ingested in the food, or in other words the exogenous protein, it must be admitted that symptoms may also arise from faulty endogenous metabolism, that is, the metabolism of the protein of the tissue cells which must be broken down into simple compounds and eliminated. Symptoms may also arise from the absorption of protein toxins of bacteria in the intestinal canal. I believe, however, that symptoms usually attributed to autointoxication really arise from the imperfect metabolism of the ingested protein.

10. The diseases which I consider protein poison manifestations include those which were classified by the old French school as caused by a lithemic diathesis. They noted the close relationship of these diseases and also the inherited tendency. With the discovery of infection, however, the term diathesis fell into disrepute and no other cause for disease than infection was entertained. Protein is also the cause of the exudative diathesis of the modern German school, and likewise of acidosis.

11. Heredity is a most important factor in protein poison manifestations, and the inability to metabolize properly is much more noticeable in some families than in others. This may be explained if it is admitted that the chemical characteristics, for instance the arrangement of the protein molecules in the tissue cells, upon which the metabolism of protein depends, are inherited, just as physical characteristics are. The disease itself is not inherited but the chemical characteristics and consequent inability to digest protein, are inherited.

12. While it is true that a certain amount of protein is necessary to replace tissue waste, it must be remembered that all protein is potential poison and unless the resistance or immunity to a particular protein is present, harm will result from its ingestion. As far as foreign proteins are concerned, the ability to metabolize them properly, and immunity are the same. As far as idiocyncrasies to certain proteins are concerned, it may be assumed for all practical purposes that those who have idiocyncrasies to certain proteins are in a measure susceptible to all proteins, or in other words, those who have idiocyncrasies are protein poison subjects.

13. Although some people have idiocyncrasies to certain vegetable proteins, and especially to the protein of fruits, it may be taken as a general law that the human race has developed considerable immunity to vegetable protein. The immunity to animal protein is much less general. In some families the lessened resistance is very marked and instead of developing from generation to generation an acquired immunity, they transmit a lowered resistance. This fact is easily proved by studying the family histories of protein poison subjects.

14. Protein poison should not be confounded with the nucleins. Protein poison is soluble and easily extracted, especially by heat. This fact is of great practical importance, though often overlooked, for meat juices, soups, and gravies contain the protein poison of the meat. In my experience I have found soups and meat extracts just as deleterious to a protein poison subject as the meat itself. The protein poison of fruits is also found in fruit-juices and jellies, as those who have idiocyncrasies to proteins contained in strawberries or oranges well know.

15. Protein poison may produce manifestations in any tissue or organ of the body and may simulate any symptoms that are produced by infection; indeed, many symptoms attributed to infection are really protein poison manifestations. It may cause inflammation, pain, fever, and edema. The symptoms vary according to the tissue involved. There may be manifestations in the skin, in the mucous membrane of the digestive or respiratory tract, in the nervous system, or in any organ of the body, including the ductless glands and organs of special sense.

16. Just as in infection, the protein poison manifestations may be acute or chronic. The acute manifestations are often accompanied by acidosis. There may not always be acetone in the urine, but titration of the urine will always show a high degree of acidity. Polyuria is often present. The blood is apt to show eosinophilia especially in affections of the skin and bronchial mucous membrane. The type of fever may simulate that of typhoid or tuberculosis. Acute protein manifestations accompanied by rash and fever are very apt to be mistaken for exanthemata. Some cases of acidosis simulate meningitis.

17. In chronic manifestations, as a result of the continued action of protein poison, organic changes in the tissues are taking place, and there is degeneration of tissue with the resulting scar formation. Although a person may become immune to the acute manifestations, or never be subject to them, still there is danger that damage is being done to a blood vessel, the kidney, or the liver, producing arteriosclerosis, nephritis, or cirrhosis, or that de-

generation and sclerosis are taking place in some other tissues of the body.

18. There is a marked tendency in protein poison subjects to abnormal acidity. If the urine of these patients is titrated it will be found that instead of being about 30, which is normal, it will be anywhere from 50 to 100. Also the saliva will often be found to be acid instead of alkaline, which it normally should be. These patients are frequent subjects of hyperchlorhydria acidosis and often are subject to lithiasis.

19. One of the characteristics, especially of the acute protein poison manifestations, is the multiplicity of the manifestations. One patient may have many different manifestations, such as migraine, hyperacidity, nasal turgescence, and be subject to attacks of purpura. Another patient may have periodic diarrhea, bronchial asthma, and suffer from various myalgias. Another may have eczema, chronic bronchitis, and gout. Another may be subject to periodic sore throats, have frequent headaches, and be subject to vertigo and ringing in the ears.

20. Variability is also a characteristic of protein poison manifestations. Instead of several manifestations taking place at the same time, as in syndromes, a patient will suffer for years with intestinal manifestations; these will cease and a respiratory manifestation such as bronchial asthma, takes its place. It is not infrequent to see urticaria alternate with bronchial asthma. A patient may suffer for years with migraine and this will cease with the beginning of a colitis or a bronchial asthma.

21. Periodicity of attacks is another characteristic of protein poison manifestations. Attacks often appear in cycles with intervals of well being. This is especially noted in children who have periodic sore throats or attacks of bronchitis, or have periodic digestive disturbances with vomiting or diarrhea. In children these attacks are often accompanied by skin manifestations such as dermatographia. The periodicity of migraine, gout, bronchial asthma, and purpura hemorrhagica, is well known.

22. The ductless glands play an important role in metabolism and it is not strange that they should suffer from protein poison. In their endeavor to meet the demands of excessive protein intake, one or more of the ductless glands is overtaxed, and the body in turn may suffer from the over-secretion of the ductless gland. Exophthalmic goiter is one example of the over-secretion of the thyroid gland, and high blood pressure with its consequent arteriosclerosis is an example of the over-taxing of the suprarenal glands.

23. The primary cause of disease is often overshadowed by the secondary cause. Infection is not the primary cause of sinus trouble, which is so often found in protein poison subjects. The primary cause is the turgescence of the nasal mucous membrane which impairs the normal drainage from the sinuses. Acute attacks of nasal turgescence with coryza-like symptoms can easily be produced in a susceptible subject by his eating too much animal protein.

24. There is also a direct relation between protein poisoning and infection. By the continued ingestion of protein, especially animal protein, in persons whose metabolism is deficient, the alkali reserve of the blood and tissue fluids is lowered. This tends to a lowered resistance to infection. Protein poison subjects are subject to acne, pimples, and boils, showing a lowered resistance to infection in the skin. These patients also are frequent sufferers from tonsillitis, cankers, and pyorrhea. If the family and personal histories of patients having ulcers of the digestive tract be studied, they will be found to be protein poison subjects.

25. One of the most interesting manifestations of inherited protein poison manifestations is the tendency to hemorrhage. The children of such subjects are liable to frequent nosebleed. The women are liable to menorrhagia and excessive hemorrhage at the menopause. Purpura is an inherited protein poison manifestation. I have traced it in families for as many as five generations. There is no strict dividing line between simple purpura, purpura with bleeding from the mucous membranes, and the complete syndrome of purpuric spots, hemorrhage, intestinal colic, hyperacidity, and malaise, often accompanied by mental depression.

26. In protein poison families there is a strong tendency to new growth. Fibroids are very common among women. The tendency to hemorrhage which often accompanies the fibroid, is more often another protein poison manifestation, and not necessarily caused by the fibroid. The occurrence of cancer almost wholly in families who have other protein manifestations is very suggestive. Though heredity plays an important role in the etiology of cancer, cancer itself is not inherited; what is inherited is the inability properly to digest protein. Thus the child of a parent with cancer does not inherit cancer, or the tendency to cancer, but cancer is certainly one of the diseases which the child is very liable to acquire.

27. The etiology of idiopathic epilepsy and insanity is far from being solved, yet the inherited tendency in these diseases, and the marked improvement in some of the milder neuroses, as well as in some cases of epilepsy, by restricting the protein intake, especially the animal protein, strongly suggests that the fundamental cause is protein poison. The family histories of these patients are also strongly suggestive.

28. Diabetes is frequently found in protein poison families and is often found in association with protein poison manifestations such as gout, eczema, migraine, hyperacidity, etc. This is a seeming paradox, but the inability to metabolize carbohydrates is not the cause of diabetes but the effect. Diabetes is very rare in Japan and among vegetable eating people. It is found principally among meat eating people and is notoriously a disease of high living. I believe the cause of diabetes will be found to be in the damaging effect of protein on the pancreas and the ductless glands.

29. In making a diagnosis of protein poisoning the personal and family history is of the utmost importance. The occurrence of protein manifestations such as gout, migraine, purpura, eczema, lithiasis, bronchial asthma, goiter, mucous colitis, sinus trouble, etc., etc., in the patient or his family should be noted. Often a patient will be found to be of a gouty family and have a history of many protein manifestations.

There are certain stigmata to be looked for, such as trophic changes in the nails shown by the longitudinal striated lines, early greyness or loss of hair, Herbeden's nodes, etc. The occurrence of many warts and moles, naevi, and telangectases is suggestive.

30. The differential diagnosis usually lies between protein poison and infection. The possibility of focal infection should never be overlooked, yet as protein poisoning will simulate all the symptoms of focal infection, it is well to take that into consideration before extensive or repeated operations. I have seen so many cases where symptoms have persisted after repeated operations (including the extraction of all the teeth) to locate focal infection, but finally disappear under restricted protein diet, that unless the infection is evident and operation clearly indicated I would give the patient the benefit of the more conservative treatment.

31. The prognosis depends upon the age of the patient and the duration of the symptoms. The best results are accomplished when treatment is commenced before any organic change has taken place in the tissues. The best results are achieved in children and young adults, though even in elderly patients the improvement is often marked. In children the prevention of protein poison manifestations is much more important than the treatment, for the acute symptoms are usually self-limited and of short duration, yet much harm can be done by improper diet if the cause of the symptoms is not understood.

32. In considering treatment it is well to remember that the researches of Chittenden and others prove conclusively that the human body can be in the best of health and strength and keep a nitrogenous balance on about one-half the protein intake that was formerly thought the minimum. The human race, especially in modern times, is habitually consuming two and three times the amount of protein necessary to repair tissue waste. Many experiments have shown that animal protein is entirely unnecessary and that the body can subsist and maintain its health and strength upon a diet in which all the protein is from the vegetable kingdom only.

33. In treating protein poison manifestations it is, in my opinion, best not to lose time by attempting to locate particular proteins, for I believe that those who are susceptible to particular proteins are also susceptible, in a measure, to all animal protein. It is best then to restrict or withdraw, according to the necessities of the case, all animal protein at once. It may be necessary to withdraw all fruit at first. The withdrawal of fruit is indicated as a result of the clinical experience that many of the exact manifestations of protein poisoning are also produced by fruits.

It is interesting to note that protein poison subjects often have idiosyncrasies to drugs as well as foodstuffs. In restricting the diet as to meat, eggs, and cheese, it must be remembered that the protein poison is soluble and easily extracted and that meat soups and gravies, and also fruit juices and jellies, contain the poison. As tea, coffee, and cocoa contain protein poisons and will produce manifestations, they also must be restricted. The amount of cow's milk taken must be limited. The fact that rabbits will die in twenty days if fed on cow's milk, although they are at the same time given their normal vegetable food, should convince the most skeptical that cow's milk contains a poison. Children must either have or acquire an immunity to cow's milk or it will produce manifestations. I believe that most of the digestive troubles of infants arise from the protein of cow's milk. It is certainly remarkable how the tendency to convulsions and digestive disturbances in children disappear when the cow's milk is restricted and gruels substituted. Although the diet is the principal factor in treatment, eliminative treatment and a certain amount of alkali are indicated. The index of acidity of the urine should not be allowed to remain above the normal. There is certainly considerable value in antianaphylaxis, that is in giving a small amount of protein an hour before meals in order to prevent the manifestations. I have used it, especially in eczema of bottle-fed babies, with very gratifying results. The work done on vaccines for particular proteins is very interesting, but I do not believe it is necessary to use particular proteins. Different foreign proteins often have like effects when used remedially as vaccines. This fact is probably the secret of the remedial effect of phylacogens and non-specific vaccines.

34. In children the results from restriction of diet are very prompt, as they also are in young adults. With increasing age the results are less prompt. For a week or two the patient may even feel much worse, because withdrawing the protein is like withdrawing a stimulant. This is very noticeable with coffee, and the same discomfort may be manifest in withdrawing animal protein. But the good results will be manifest in time except in those cases in which organic change has already taken place, and even in those cases improvement may appear in time. It is a law in nature that disturbance of function precedes organic change and that the timely removal of the cause of functional disturbance will prevent the organic change. The best results therefore in applying the principles of this paper should be in the prophylaxis of organic disease.

35. Protein poisoning manifestations are of especial importance to the pediatrist because the principles can be applied before much damage has resulted. The dermatologist finds abundant opportunity to apply the principles in the many manifestations of the skin. It will interest the oculist, for protein poisoning is very probably the cause of many obscure lesions of the eye. Protein poisoning is of the greatest interest to the obstetrician, for it is undoubtedly the cause of the toxemias of pregnancy. The alienist should study epilepsy and insanity with a view to protein as a cause.

The relation of protein to infection opens a wide field of investigation. For instance, poliomyelitis attacks certain children and for no apparent reason others escape. If it could be shown that the children of those subject to protein poison manifestations are more susceptible to this infection, some clue would be had to the cause and prevention of this dread disease.

In the study of any disease of obscure origin the possibility of protein as a cause should be considered. For example, it is strongly suggestive that

the Hindu and Indian troops, who do not eat meat, never have trench nephritis, but it is very common among the French and English troops, who are heavy meat eaters. The exposure to wet and cold lowers the resistance to the protein poison and limits the efficacy of the skin, with a resulting nephritis as a protein poison manifestation.

Pernicious anemia and other diseases of the blood will undoubtedly find a solution in this cause. It is impossible in this short synopsis to cite the animal experiments, or literature, or wealth of clinical cases upon which the apparently dogmatic statements in this paper are based. The very simplicity of the theory makes it seem unbelievable, but if the principles upon which it is founded are put to trial the results are so evident that the fact that the protein of food causes disease must be accepted.

The realization that the protein of food is a cause of disease as well as the cause of symptoms throws new light upon the whole study of medicine. At first it seems paradoxical that the cause of disease should be founded upon the law of self-preservation and that each animal and plant contains a substance that is poisonous to other animals and plants until they develop an immunity, or ability, to digest it without harm to themselves. The poison is always in the protein, the ability to metabolize is the variable quality, and the absence of this ability results in disease. The cause of disease is therefore found in the very food upon which the body depends for its sustenance. In this paper I have endeavored to give a brief synopsis of a subject upon which volumes could be written. I have endeavored to present the idea only. It conflicts with nothing that has so far been written in medicine and explains much that has not been understood. By the application of its principles much suffering will be relieved, but the greatest good will be accomplished in the prevention of disease.

Base Hospital No. 22, Am. Ex. Force.

A CASE OF CIRCUMFLEX NERVE PARALYSIS FOLLOWING A CARBUNCLE.

By LUCIUS FELIX HERZ, PH.B., M.D.,

NEW YORK.

CLINICAL ASSISTANT IN SURGERY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

W. G. M. was first seen by the writer on December 4, 1917, and then was suffering from several small furuncles of the back of the neck. The skin around these was irritated from a home-made poultice of soap and sugar. Previous history was inconsequential, except for rather marked alcoholic history. The man was of short, thick-set build, and weighed 225 pounds.

Patient feared any operative procedure, so treatment consisted of small incisions followed by Bier's suction cup. Much pus was thus evacuated and a pronounced hyperemia of the surrounding skin produced. The original furuncles quickly healed under this line of treatment, but new ones seemed to develop constantly in entirely different locations, and it seemed that as fast as one healed another was ready to replace it. Finally a large furuncle formed in the center and rapidly invaded the cellular tissues of that location, speedily attaining the character of a carbuncle. Palliative measures, such as curetting the center, applying tincture of iodine, using hyperemia, etc., were of no avail, and radical operation was advised. It took two days before the patient would give his consent, although I impressed upon him that it would soon be a matter of life or death, and further delay would absolutely prove fatal. Chills and a temperature of 101.6° now existed, the tenderness and swelling involved the entire neck, and the patient stated that "it had gone up so high that he could not put his derby hat on"; he meanwhile felt so ill that he gladly consented to operation.

Operation was performed by the writer on December 21, at Flower Hospital. General anesthesia was used. Gas induction was attempted, but caused an epileptiform convulsion followed by cessation of respiration. The patient was soon revived and straight ether given. The operation consisted of a simple crucial incision and undermining the flaps with Mayo scissors. Considerable pus, under pressure, was evacuated. Iodoform packing was inserted and wet dressings of chlorazene used.

The after treatment consisted of a twice daily dressing, irrigating with half strength peroxide, and renewing dressing as previously described. The temperature dropped to 99°, and soon became 98.6°. The patient was discharged from the hospital on the sixth day.

The following day the patient's temperature rose to 103.2° by mouth, and he complained of excruciating pain in the rectum, extreme dysuria, tenesmus, and increased frequency. The urine was loaded with pus. Rectal examination revealed an extremely large and tender prostate. Secretion from the same was also loaded with pus. Patient admitted having had gonorrhea five years before with a complicating prostatitis, but was discharged as cured by a recognized genito-urinary specialist. A mixture containing potassium citrate and tincture of hyocyamus was given every four hours. A large amount of water was ordered by mouth. Rectal suppositories of opium and belladonna were also given. Patient recovered from this complication in a week, treatment being as outlined, combined with local treatment by bladder irrigations of potassium permanganate, and gentle prostatic massage.

On January 2 the patient complained of rheumatic pains in the right shoulder. Wet dressings were stopped and balsam of Peru drains used in dressing the carbuncle. Aspirin gr. xv, given every three hours did not relieve the rheumatism. On January 15 both shoulders were involved, the left seeming to be more superficial than the right. Aspirin, although pushed to the limit, having caused no relief, the possibility of a gonorrheal arthritis was considered, and the writer was about to try antigonococcus vaccines, but the patient had a foolish prejudice against vaccines, so I was unable to use this line of treatment. Atophan in 7½ grain doses was next given four times daily. This caused slight relief.

On January 15 the wound was entirely free from pus, the granulations were a healthy red, and the treatment from now on consisted of daily dressings of scarlet red ointment.

On February 1 the carbuncle wound was entirely healed. The rheumatic pains continued in both shoulders as before. Atophan continued.

On March 1 the patient was seen again. The pains had entirely left him, but he now had a complete paralysis of the right circumflex nerve, with atrophy to a slight degree of the right deltoid muscle as evidenced by a drooping of the shoulder. The power of abduction was entirely absent in the right arm. He retained full use of the other muscles of the arm. He received electrical treatment for this at the Neurological Department of the Post-Graduate Hospital, and had this supplemented by exercise on pulleys, and by massage at home. Rapid improvement followed the treatment, and the patient when last seen, on April 30, could readily abduct his arm to a right angle, and had very nearly recovered its full use. At least now he is able to perform all necessary duties.

The only explanation that I have to offer of this strange paralysis is that it was caused by a toxic neuritis excited by the pus in the blood-stream. Evidently there was not sufficient pus in the blood to cause a general septicemia, or phagocytosis was well established to guard against this. The pus that had been wont to form furuncles and finally the carbuncle, sought any place of lodgment having a lowered resistance. First it lodged in the prostate that a previous gonorrheal prostatitis had weakened.

After this subsided, it traveled to both shoulders, and produced a simultaneous rheumatism and neuritis of the circumflex nerve. The neuritis explains the pain that antirheumatic measures failed to stop.

The neuritis then caused a degeneration of the circumflex nerve, and this produced an atrophy of the muscle supplied by it—the deltoid. Injuries of the shoulder, such as fracture of the neck of the humerus or dislocation of the humerus, frequently produce a degeneration of this nerve. Pyemic processes rarely do so, and that is my reason for reporting this case.

438 West Forty-fourth Street.

Medicolegal Notes.

Liability of Charitable Hospitals.—In an action against a charitable hospital for the death of a pay patient which it was alleged was caused by the negligence of the hospital and its servants in allowing her to fall from a window, the Kentucky Court of Appeals discusses exhaustively and reviews the authorities upon the subject of liability of charitable hospitals to their patients. The following is an abstract of the court's opinion:

"An examination of the authorities has convinced us that a purely charitable institution, such as defendant's hospital is described in the pleadings to be, is not amenable to its patients, although paid ones, for any damages which they may have sustained growing out of alleged negligence, although such negligence might consist in the violation by the hospital of some duty imposed either by an express or implied contract. The cases dealing with the subject seem to treat the cause of action as sounding in tort, although the liability, if any, was created by the negligent failure on the part of the hospital to observe some contractual duty, which is analogous to the rule applied to common carriers in suits by their passengers who sustain contractual relations the one with the other, although the suit is generally treated as one sounding in tort. Bearing this in mind, we find the rule whereby such institutions are absolved from liability thus stated in 13 R. C. L., p. 945: 'Immunity in all cases of tort has been claimed for them on the following grounds: (1) Public policy; (2) that the assets or funds of the institution are impressed with a trust for charitable purposes and may not be diverted to other use; (3) that in so far as concerns patients voluntarily entering, whether as pay or as charity patients, they impliedly waive all claim for injuries and assume the risk thereof.' The editor then proceeds to discuss each ground of nonliability, and in the notes to the text are cases from almost every state in the Union, as well as from the federal courts, relieving the institution from liability, even in the case of pay patients who thus sustain contractual relations to the hospital. But the courts are not unanimous concerning the particular ground upon which they base their opinions holding the hospital not liable. Only two courts, so far as we are advised, reject all three of the grounds and hold the hospital liable to its pay patients for an alleged negligent failure to comply with the contractual terms under which the patient was received; they being Alabama, in the case of Tucker v. Mobile Infirmary Association, 191 Ala. 572, 68 So. 4, L. R. A. 1915 D, 1167, and the Ontario Supreme Court in the case of La Vere v. Smith Falls Public Hospital, 26 Dominion Law Reports, 346.

"At one time the Supreme Court of the State of Rhode Island joined the small band of courts who repudiated all grounds of nonliability of such institutions, as is shown by the case of Glavin v. Rhode Island Hospital, 12 R. I. 411, 34 Am. Rep. 675. But the succeeding Legislature of that State, at its 1882 session, promptly renounced that doctrine and enacted a statute excusing the institution from such liability, but preserving the right against the particular servant guilty of negligence.

"The first ground found in the excerpt from R. C. L., supra—that of public policy—upon which a number of courts base their opinions holding the defendant in this character of case not liable, is upon the theory that such institutions are inspired and supported by benevolences and devote their assets and all their energies to the relief of the destitute, the sick, and the needy, and that the common welfare requires that they should be encouraged in every way and be exempt from liability from this character of action; that if it should be otherwise held, it would operate to discharge the charitably inclined from donating or founding such institutions and might utterly destroy them, thus indirectly casting the burden of doing so upon the State. * * *

"The trust fund doctrine proceeds upon the idea that the trust created by the founders of the institution as augmented by receipts from pay patients constitutes a charitable trust fund, and that, if it should be diverted to the payment of judgments which might be obtained in damage suits against the institution, the purposes of the charity, as well as its donors, would be frustrated, and the charity itself most likely eventually destroyed, and that such a result was never contemplated by its founders or those who in any manner donated to the institution. * * *

"The theory of the 'implied waiver' doctrine is that one who accepts the benefits, accommodations, and services of such an institution enters into a relation with it whereby he agrees to exempt it from liability for the negligence of any of its servants in administering the charity, and that the patient thereby assumes the risk growing out of any negligent act of any of those connected with administering the affairs of the institution. * * *

"Text-books and other treatises holding a purely charitable institution of the nature of the defendant here immune from liability for this character of suit are: 2 Cooley on Torts, pp. 1011-1013; Jaggard on Torts, vol. 1, pp. 184-187. These works base the nonliability upon the same ground that State institutions engaged in a like service are excused, in that the private but purely charitable institutions are performing a necessary duty which, if not done by them, would in all probability have to be performed through some arm of the State.

"While not called upon to take a position relative to the merits or demerits of all of the three respective theories above referred to as grounds for excusing the institution from liability in this character of case (althought the first and second ones have been adopted by this court), we are not averse to saying that each of them to our minds is founded upon sound logic and convincing reasoning, and while caustic criticism of each of them will be found in some of the opinions, although the same opinion adopts one or other of them, such criticisms appear to lose sight of the nature and purpose of the defendant and treat it in applying the principles of the law as though it were strictly a private institution. * * *

"Some of the cases referred to relieve the defendant of liability on the ground that the doctrine of respondeat superior does not apply to purely charitable institutions, but we have not dealt with this feature of the case, since the conclusion which we have reached renders it unnecessary. Neither have we overlooked the fact that some of the cases relieving the institution of liability impose upon it the duty of exercising care in the selection of their servants, for which, if they should negligently fail to do, they would be liable. But we have found it unnecessary to consider that proposition, because there is no allegation presenting that issue. Nor do we pass upon the question of the liability of such institutions for conduct purely tortious, affecting members of the public who are strangers to them. We would also not be understood as holding that such institutions would not be liable on their contracts made for the purpose of protecting, looking after, and taking care of their private property, or in supplying themselves with those necessities required for their continued maintenance, since upon such contracts they are liable, as are other individuals and corporations."

Judgment for the defendant was affirmed.—Cook v. John N. Norton Memorial Infirmary (Ky.), 202 S. W. 871.

Military Medicine.

WAR WOUNDS OF THE TONGUE.

Injuries to the tongue in warfare may follow upon contused wounds of the face with fracture of the lower jaw, but more commonly the lesions are due to the missile itself, or to bits of bone or broken teeth. Rifle bullets, but especially bits of shell, produce shattering of bone, resulting in furrows, perforation, or loss of tissue of the tongue, and all such injuries, which in reality represent contused wounds, frequently result in irregular cicatrices. But even when extensively involved, the tongue usually recovers its functions well, both motor and sensory. The complications of lingual injuries may, for convenience, be divided into (1) *primary* complications, which include vasculonervous lesions and foreign bodies (bits of all kinds, missiles or teeth), (2) *secondary* complications, which are always septic in nature, and (3) *late* complications, represented by defective cicatrices.

As to vasculonervous injuries, it may be said that although the nerve trunks are frequently divided, it is rather curious to note that following suture of a more or less extensive division both mobility and sensibility appear to be almost intact. Among arterial wounds the most serious are those of the base of the tongue. When the wound is large hemorrhage is manifest, but when the wound is narrow, or if occluded by blood clot, a diffuse aneurysm may develop, resulting in tumefaction of the organ, and the swelling may be so great that serious dyspnea and dysphagia ensue; but the situation is made still more grave by the septic processes which are prone to arise in the traumatic focus.

Suture should be done in every case of deep wound, even if contused, or if the tongue is almost completely divided. Should the wound be several days old, the edges are to be freshened and secondary suture performed. The sutures should be interrupted, and catgut is to be used in preference to other material. The suture is usually sufficient for the control of small hemorrhages. In the case of larger vessels, ligature of the divided ends in the wound should be essayed, although this technique offers considerable difficulty in wounds at the base of the tongue. In order to facilitate the operation the tongue should be drawn well out of the buccal cavity, and, if necessary, the organ can be rendered more free by cutting around it with scissors. In these circumstances, general anesthesia is essential. When extensive damage has occurred, which makes it practically impossible to search for the injured vessels, the lingual artery may be tied in the neck, or, still better, the external carotid, when any doubt exists as to the vessel involved.

Wounds from firearms result in the lodgment of bullets, bits of bone, teeth, fragments of clothing, etc., in the lingual mass. All these bodies are projected into the organ, and may remain embedded in its tissues, and it is far from always being an easy matter to detect them. Radiography gives us the necessary data in the case of metallic bodies, but on account of the mobility of the tongue their exact localization is almost impossible to obtain. As to teeth and bits of bone embedded in the tongue, the *x*-ray is powerless to give exact diagnostic indications, so that the surgeon must rely upon the pain and tumefaction, with all its functional consequences, as a guide to diagnosis. However, it is to be remembered that a foreign body may become encysted and be tolerated by the tissues for years. In other instances an acute inflammatory process arises, resulting in fistula, while the suppuration results in the secondary elimination of the foreign body.

The septic complications encountered in wounds of the tongue are deep seated; in other words, the process is a phlegmonous glossitis. This condition of affairs is set up by an infectious process, the result of the presence of a foreign body. Treatment consists in deep incisions, and if gangrene is present the incisions should be made with the thermocautery. The after treatment consists in frequent buccal irrigation with a solution of chloral.

The late complications are represented by adhesions following the cicatrization of the traumatic focus, and are not uncommonly accompanied by serious destruction of the lower jaw. Adhesions situated on the floor of the mouth appear to be the most frequent. They hinder phonation, mastication, and deglutition. The treatment is rather simple in most cases. When the adhesion is limited in extent all that is required is to excise it and then prevent its recurrence. But when the adhesions are extensive, and especially when total ankyloglossus has taken place, the operative results are disappointing, because the adhesions almost always recur. Perhaps the best way of preventing this unfortunate event, when it is possible, is to excise all cicatricial tissue and then suture in healthy tissue.

Protection of the Sight of the Combatants.—Putelli (*Giornale di medicina militaire*, February 28) covers this subject from a special angle—the consequence of an enfilading fire upon the orbitotemporal region, which is unprotected by the helmet. The first thought to occur in this connection refers to the possibility of extending the helmet to protect the above mentioned area, including the ear and nose and even the jaws. Implication of the orbit in wounds of the face is extremely common and bullets in the orbit often penetrate into the nasal structures—so that there is a special type of orbitonasal wound. Injury from enfilading fire differs radically from wounds received full in the face, for only too frequently in the latter the projectiles prove lethal by penetrating into the brain.

In wounds from enfilading fire one eye only, as a rule, is menaced, although the projectile often enough makes its exit on the opposite side of the face. Of eighteen orbital cases given by the author in only four was the sight of both eyes lost. On the other hand, it is not uncommon for wounds in the temporo-orbital region to spare the eye, and the author cites a number of such cases in which the course of the projectile either did not involve the orbits or in case of such involvement—as in exit wounds—spared the eyeball and optic nerve.

The author, who is an otorhinologist, has no direct knowledge of the consequences of wounds involving loss of vision, save in accidents in which

the nose and ear likewise suffer. The prophylaxis of wounds from enfilading fire, whatever the nature of the projectile, is sufficiently obvious. The helmet should have a flap which is not unlike the ear laps of a winter cap in its area save that a strip runs forward in the region of the frontal sinuses. The nature of many of the wounds is such that the metallic flap would have prevented or minimized them. Helmet protection is of course limited at best, but the chief aim here is protection of vision rather than from traumatism. Infantry bullets at long range, ricochet bullets, small fragments of explosive shells, are the classes of projectile in which protection is chiefly secured. In enfilading wounds, however, another element, viz., the tangential impact of a bullet must be had in mind. These protective metallic flaps should be able to deflect many a tangential projectile.

Although the author gives photographs of men wearing the new extension helmets it does not appear that they have actually withstood the test of battle. Before their adoption certain weighty matters had to be settled. Do these flaps interfere with the visual field in any way? Do they in any way prejudice the use of the gas mask? The questions are at once answerable in the negative. Moreover, as the author states, the flaps are "polyvalent," for in addition to the eye, they afford protection for the ear and nose.

Prevention of T. N. T. Poisoning.—An immediate result of the absorption of T. N. T. into the system, whether through the skin or otherwise, is a chemical change in the hemoglobin of the red blood corpuscles which shows itself in a pallor or duskiness of the skin with blueness of the lips. This cyanosis does not by itself produce fatal results and if fresh entry of the poison is prevented the body rapidly recovers. But if the effects are permitted to accumulate two incurable and rapidly fatal diseases may occur, namely, "toxic jaundice" as a result of the destruction of liver substance, or more rarely "aplastic anemia," due to the blood forming organs failing in their function so that a progressive loss of blood takes place. These diseases, however, do not always result from even severe cyanosis; while, on the other hand, there seems to be evidence that they have developed without that danger signal first appearing. Different persons have vastly different susceptibilities, very many are quite immune. Thus one of the main causes of the decreased incidence of the disease in 1917 as compared with 1916 is that workers whose powers of resistance are small have taken up other work. The investigation which was carried out by Dr. B. Moore, also showed that the main source of absorption was through the skin and not through the respiratory organs. Not only is T. N. T., which is breathed in as dust in the air, much less harmful than that rubbed in the hands and forearms, but also the amount absorbed per shift is small and easily ejected from the system. Elaborate methods of ventilation are not so necessary as skin protection. The hands and face can be covered effectually by casein and varnish, while the legs and feet must be protected by suitable boots.—*British Science Progress*, April, 1918.

Government to Mobilize All Doctors.—It is reported that a plan is under consideration whereby the Government may assume control of the entire medical profession in the United States in order to obtain sufficient doctors for the army and so to distribute those remaining that their services may be rendered in those places in which they are most needed. Instead of enrolling in the Voluntary Medical Service Corps only those physicians not suitable for military service, either because of age, physical infirmity, dependency, or institutional or public need, the plan will probably be to throw open the membership to all doctors and to bind them with a pledge "during the present emergency to accept service, military or civilian, wherever, whenever, and to whatever duty they may be called by the central governing board. The practical operation of this plan, officials believe, would cause little relocation of doctors, since physicians who are needed in certain communities would not be commissioned in the army. Conferences were held in Washington, on July 18, and in a number of other cities to discuss the operation of the voluntary enrollment plan. A plan is being considered by the Surgeon Generals of the Army, Navy, and Public Health Service for commissioning all teachers in the medical schools and assigning them to their present duties for the purpose of preventing further disruption of medical teaching staffs and at the same time recognizing the public service of those men.

Deliberate Bombing of Hospitals Continues.—A report from the American Army on the Marne, under date of July 15, states that Germans deliberately attempted to shell several of the American hospitals behind the lines near the Marne front on that date. The shells in this instance, however, did no damage. An attack made the following night on the American Red Cross Hospital at Jouy did not terminate so fortunately. Two enlisted men were killed and among the personnel nine persons were wounded. Several doctors were performing operations at the time, and notwithstanding the explosions continued with their work. At least three bombs were dropped on the hospital. Additional doctors were telephoned for and the work of the hospital continued without interruption. This same night was a busy one for the Red Cross Hospitals being evacuated in the region of Châlons. The hospital at Jouy recently had among its wounded sixty German prisoners. They, of course, received exactly the same treatment as the other patients.

Guarding Camps Against Flies and Mosquitos.—Special attention is being given to cleaning up spots near camps where mosquitos and flies breed. There is attached to each camp a division surgeon who has as an assistant a sanitary inspector who, in turn, has the assistance of a sanitary engineer and from 100 to 200 enlisted men employed in work designed to protect the health of soldiers. They have in some places put in elaborate ditching systems and where this has been impossible slow moving streams and still bodies of water are kept covered with oil. At all points within the camp where there is a possibility of mosquitos or flies breeding daily spraying with oil is done. Arrangements have been completed with the Public

Health Service for carrying out this plan for a radius of one mile around all camps. Arrangements have been made to protect all food from flies; all buildings in which food is prepared or stored are screened, and an average of 6,000 fly traps are placed in each camp. More than 22,700,000 square feet of screening has been placed in all camps.

Clinic for Disabled Soldiers, Sailors, and Civilians.—A clinic affiliated with Cornell University Medical College was opened, on July 15, at 5 Livingston Place, where soldiers, sailors, and civilians will be given functional re-education. The clinic will also provide an opportunity for instruction to medical officers and students in the methods which have been developed along this line which constitutes practically a new branch of medical science. Beds for thirty patients are provided in the hospital. A part of the equipment will consist of electrical apparatus for the diagnosis and treatment of nerve, muscle, and joint affections, which has been standardized for the Canadian and United States military hospitals. Dr. W. Gilman Thompson is director of the clinic. Treatment will be free for those unable to pay. The buildings for this clinic have been leased from the New York Infirmary for Women which has been temporarily discontinued.

Red Cross Gifts.—The American Red Cross has arranged to despatch to Russia a special ship with a cargo of supplies to be distributed under the jurisdiction of the Red Cross Commissioners now in that country. The cargo consists largely of food, clothing, and medicine for the civil population and returning refugees and prisoners.—The Scottish Women's Hospitals has been the recipient of another gift of $150,000 in recognition of its very efficient work at the front in France during the past two months.—In order to be prepared to care for the French and American wounded in the drive begun on July 18, the American Red Cross on that date sent seven tons of surgical dressings and five tons of special diet foods to the principal evacuation hospitals of the American Army. The Red Cross Medical officers' storehouses and pharmacy will operate night and day during the drive of the French and Americans. Three hundred and fifty beds with American surgeons and nurses have been added to the American Red Cross Hospital at St. Pol for use during the present offensive. The tent hospital outside of Paris has added 300 beds.

Women Anesthetists for Army Service.—It is said that many wounded soldiers prefer the care of women attendants and that for this reason the army is appointing women anesthetists. Fifteen have already been appointed, receiving the pay and privileges of First Lieutenants without, however, the actual rank. Only graduate women physicians are eligible.

American Dentists "Doing Their Bit."—The preparedness League of American Dentists, comprising more than 15,000 dentists who have pledged themselves to give at least one hour of their time daily, including materials, to men selected for the Army, Navy, and Marine Corps, reports that 500,000 free operations have already been performed. The League is supplementing the work of the army in making recruits dentally fit, and in this way puts many men into the service whose acceptance would otherwise be delayed. There are 48,664 dentists in the United States and the League is trying to obtain a 100 per cent. membership at $1 a year. The League is divided into six military departments headed by a director for each department. Each of these directorates is in turn subdivided and managed by a director for each State.

Women's Ambulance Units.—The National League for Women's Service is making a drive to obtain fifty ambulances to be driven by its motor corps in transporting wounded men returning from the front to base hospitals in New York. The Surgeon-General has requested the women to be ready to begin work by the middle of August. The Yale Club has donated the first ambulance. Sixty women have formed the Queens Company of the Red Cross motor service and will drive ambulances to and from the base hospitals in Queens. The first ambulance was installed on July 19 and assigned to Far Rockaway. An ambulance for Long Island City, costing $550, has been donated by Mrs. George Hanavan. The women ambulance drivers must hold a chauffeur's license and have had fifteen hours first aid training.

Claim Cure for Gas Gangrene.—A special cablegram to the *Chicago Tribune* announces that Professor Vincent recently read a paper before the Paris Academy of Sciences in which he described a serum which he has prepared which has been effective even in severe cases of gas gangrene.

Hut Hospitals Reach England.—The first shipment of 150 hut hospitals, which the American Red Cross has built in the United States for use in eighty small camps throughout Great Britain, have arrived in that country. They will be immediately set up as camp dispensaries, isolation hospitals, and convalescent wards at aviation camps in England. The huts could not be constructed in England on account of the shortage of lumber without crippling important war work, so they have been shipped in knock-down form.

American Zionist Unit Welcomed.—The American Zionist Medical Unit which is on its way to Palestine stopped in London recently where a large meeting in its honor was held in the London Opera House on July 15. Lord Rothschild presided.

Low Venereal Disease Rate.—The War Department reports that the spread of venereal disease has been greatly reduced among the American Expeditionary Forces by the methods employed by the Army Medical Corps. The lowest record for the Army was in 1916, 91.23 per thousand. The latest report shows the present rate to be 47.8. Among the troops in the United States the rate has been reduced approximately to 21 per thousand yearly.

The Carlisle Indian School to Be a War Hospital.—The well-known Indian school at Carlisle, Pa., originally an army barracks and loaned to the Interior Department for educational purposes, is to be taken over again by the War Department for use as a hospital. It will be converted into a rehabilitation hospital where war cripples can be taught various trades and occupations and be fitted with suitable prosthetic apparatus.

MEDICAL RECORD.

POSTOPERATIVE GASTROINTESTINAL HEMORRHAGE.

WHEN, after an abdominal operation, blood is vomited or voided per rectum, or the signs of an internal hemorrhage are manifest, it is essential to distinguish between gastrorrhagia and enterorrhagia, as well as to recognize the pathogenesis of the accident. The fact that there is hematemesis or melena, especially when it is in moderate amount, does not of necessity imply that the blood comes from the stomach or intestine, because a posterior epistaxis may perfectly well simulate a gastrointestinal hemorrhage and a similar mistake may occur in the case of hemoptysis when the blood is swallowed. In some cases, on the other hand, the blood is not eliminated, although there exists a gastric or intestinal hemorrhage of such intensity that death results.

The etiology of these hemorrhages, although at first glance it might appear simple, is in reality complex, and becomes still more so when it is necessary to decide if the loss of blood is the result of long standing lesions of the vascular system, of the liver, of the kidneys, or of the blood itself. No diagnostic means should be overlooked, either general or local, and in enterorrhagias, where the blood is eliminated in an almost pure state rectal examination should always be resorted to because the hemorrhagiparous lesion may be discovered within the gut. In spite of everything, in the genesis of certain postoperative gastrointestinal hemorrhages, it will often be difficult to determine the exact part played in the process by some long-standing conditions, most usually hepatic, and that due to some new factor of a toxic, infectious, or mechanical nature. However, in most cases a careful examination of the patient will offer sufficient data to make it evident at least that the hemorrhages do or do not depend upon either local or general processes of long standing.

When the loss of blood is not due to some former process, an endeavor must be made to interpret the pathogenesis of the postoperative complication. If the hemorrhage follows a surgical interference other than in the abdomen, the pathogenesis will be readily recognized because only a general infective process, intoxication, the anesthetic used, or postoperative gastric dilatation can be in play. The clinical picture of the latter process will easily reveal the nature of the case, while immediate postnarcotic vomiting, the absence of inflammatory reaction in the wound, and negative results obtained from blood-culture, will all point to poisoning by the anesthetic. In gastrorrhagia or enterorrhagia following operations in the abdominal cavity, if evidences of infection or intoxication are present, these will be so distinct that the diagnosis is made at once. Nevertheless, even then one should ascertain whether traumatic gastrointestinal lesions or lesions of the omentum may not be the etiological factor of the hemorrhage, because one is rather apt to attribute too much to septicemia or toxemia.

By carefully recalling all the details of the operation and reviewing all the symptoms offered by the patient, the exact diagnosis will usually be reached. The characters of the hemorrhage are important in themselves in this respect and the time of the first appearance of the loss of blood is, in particular, of the greatest diagnostic value. No matter what may have been the abdominal or gastrointestinal operation, this particular point retains its importance because the later the loss of blood arises, the less is the possibility that it results from a direct traumatism to the digestive tract or to an incomplete hemostasis. Poisoning by the anesthetic usually sets up early gastrointestinal hemorrhage and the same may be said of acute postoperative gastric dilatation.

The prognosis is subordinated to the quantity of blood lost, as well as to the gravity of the symptomatic ensemble, but in a general way it may be said that it is to be the more reserved in cases where the operation was not upon the digestive tract. Late occurring hemorrhage is a more serious condition than one arising shortly after the surgical intervention.

AN ALLEGED EPIDEMIC OF BOTULISM.

AMONG the diseases or conditions to which attention has been directed recently in England is that which, for lack of a more definite appellation, or because its obscure points have not as yet been sufficiently elucidated to admit of a name altogether in keeping with its etiology or symptoms, the term "botulism" has been affixed.

According to the London correspondent of this journal, June 15, 1918, the name botulism is a misnomer, in that the latest accounts of outbreaks in England do not seem to confirm the supposition that it is an intoxication caused by the products of the *Bacillus botulinus*. While the etiology of the epidemic in certain parts of England and in Paris appears to be wrapped in much obscurity, its clinical features resemble some types of infantile paralysis so closely that many observers in Great Britain

regard it as clinically identical with that disease. Indeed, Dr. F. G. Crookshank, who has had under his care at a general hospital in suburban London several cases of the ill-defined malady, has given it as his opinion that it is poliomyelitis. In Paris the epidemic has occurred chiefly among children, a circumstance which would seem to bear out Crookshank's views. On the other hand, some London medical men have not only found the symptoms of cases which came under their care identical with those of botulism, but these symptoms supervened upon the ingestion of sausage or canned food. Consequently, a good deal of confusion exists. However, it does seem a somewhat suggestive coincidence that the disease should have become prevalent at a time when the consumption of canned food is almost universal.

In view of the fact that there is not a little want of exact knowledge with regard to botulism generally, it will be interesting to refer to a very complete article on the subject read by Capt. E. C. Dickson, C. A. M. C., at the annual meeting of the Canadian Public Health Association, held in Hamilton, May 27 and 28, 1918, and published in the *Canadian Public Health Journal* for June, 1918. Among other interesting facts in connection with botulism noted by Dickson is that accurate knowledge that the intoxication may be caused by the ingestion of foods of vegetable origin dates only from December, 1913, when there was an outbreak of the botulism type at Stanford University in which twelve persons were poisoned by eating a salad prepared from home-canned string beans. Experiments then undertaken conclusively established the fact that the toxin of *B. botulinus* may be found in mediums prepared from peas, beans, corn, asparagus, artichokes, peaches, pears, apricots, and prunes.

As for the symptomatology of botulism, it differs from the usual types of food poisoning in that the intoxication essentially involves the central nervous system. Moreover, the condition is not an infection, but a true intoxication, the poisoning being produced by a bacterial toxin which is formed in the food before it is eaten, and which is ingested with the infected food. The toxin is never formed within the body, and differs from the toxin of diphtheria in that it is not digested in the gastrointestinal tract, but is absorbed, unchanged, into the blood stream. The symptoms are those of profound disturbance of the central nervous system, commencing with a sensation of languor and fatigue. A striking feature of the botulism intoxication is that there is no disturbance of mentality, and that sensation remains intact. The temperature is usually subnormal, the pulse soon becomes rapid, and the combination of a temperature of between 96° and 97° F. with a pulse rate of over 130 is very characteristic.

According to Dickson, the mortality in European cases, occurring during a period of over one hundred years, is about 40 per cent., but in the United States, probably because only the severe cases are recorded, the mortality has been between 65 and 70 per cent. In the English epidemic there have not been sufficient cases recorded to provide any very accurate statistics, but from accounts to hand it does not seem nearly so deadly as true botulism, described by Dickson. That observer also states that in this country the intoxication has been almost wholly due to the ingestion of home-canned foods, because in the United States commercially canned vegetables are sterilized with steam under pressure at a temperature of from 240° to 250° C. Furthermore, the freedom from contamination of commercially canned fruits which are canned at lower temperatures, is probably dependent upon the fact that only carefully selected, hand-picked fruit and vegetables are canned.

If such is the case, the English epidemic can hardly be due to imported canned vegetables, and unless home canning is carried on to a considerable extent in England, suspicion may be largely removed from canned articles of diet as prominent factors in the causation of the disease there. Therefore, the contention of Crookshank that the many cases observed in London and vicinity within the past few weeks belong to the category of poliomyelitis will be strengthened. The British Medical Research Committee is at the present time prosecuting a scientific investigation for the Local Government Board of the outbreak, so it will probably not be long before some of the obscure points will be cleared up.

TONSIL OPERATIONS.

It is a healthful sign of progress that tonsil operations are no longer lightly undertaken, and that there is a keen understanding of the dangers that go with these operations. Tonsil operations are now justly given the same weight as major operations. According to some observers about one-third of the cases of suppuration of the lungs are directly traceable to tonsil operations; and this complication is by no means the only eventuality to be dreaded. But it is not to be wondered at that suppuration is common after removal of the tonsil when it is remembered that this operation must be undertaken in an open septic field with no possibility for maintaining aseptic conditions. The operation of enucleation of the tonsil has helped to reduce the area of infection over the area produced by mere cutting through the tonsil as is done in tonsillotomy. Besides, but at best the operation is a bloody one. The hemorrhage is too frequently left to itself, and only when it is marked and dangerous is there any attempt made to control it. There can be no provision made for catching the blood that flows from the field of operation, and it is allowed to run whither it will. In adults with hard fibrous tonsils the blood vessels stay agape and the hemorrhage is very likely to be more severe than in children. When general anesthesia is employed there is very little ability to expel blood that enters the respiratory passages, and the blood with its load of or-

ganisms is very apt to find lodgment in the bronchi to set up suppurative processes. Moreover, the gaping blood vessels of the peritonsillar tissues encourage primary embolism of the veins. The emboli find their way directly through the right heart to the branches of the pulmonary arteries and their distributions. The same result may be achieved by phlebitis in the peritonsillar vessels and secondary embolism following the same lines as in primary embolism. Improved methods of anesthesia and more refined technique of operation reduce much of the danger, but not nearly all, by any means. Although general anesthesia adds to the dangers of tonsil operations, nothing but general anesthesia can be used in children or in adults of nervous disposition. Much of the aspiration effects following upon the hemorrhage would be obviated by the use of local anesthesia, but for the fact that because it is impossible to gauge accurately the amount of the anesthetic absorbed, local anesthesia is very treacherous in its action, and fatal outcomes are not uncommon with it.

On the whole the question of operating at all, the kind of operation, and the form of anesthesia must be decided according to the individual variations, and no rule can be laid down to cover all cases. But in all cases the tonsil operations deserve a great deal more caution in their execution than is still accorded them. The danger is so real, and the outcome so uncertain that it has been recommended, at least for adults, that the tonsil be destroyed with the high frequency spark, at several sittings. In such cases there are little reaction, little inconvenience, and little danger. None of the dangers in tonsil operations should, however, prevent their execution where necessary. All surgical operations have an element of danger, but the danger will be reduced by a proper conception of the gravity of the operation, and will stimulate improvements therein.

BLOOD TRANSFUSION IN FRANCE.

According to Professor Guyot, writing in the *Journal de médecine de Bordeaux* for May, transfusion of blood is now the order of the day. It has risen from its ashes, so to speak, and has been called on during the present war to render important services. In a recent circular, the high command of the medical body has called attention to the subject in making special provision for blood donors. The author is specially interested in the technique of his colleague, Professor Jeanbrau of Montpelier.

Modern transfusion was introduced from America by Carrel, and in 1914 nineteen transfusions were performed by Guilhot and Dehelly. Professor Tuffier was a sponsor for the new procedure. The total number of transfusions reported in France in 1914 was forty. It was not until 1917 that Professors Hedon and Jeanbrau gave to France a special technique of its own. The Carrel-Tuffier technique was modified from that of Crile. The original apparatus of the latter was brought from America by Guilhot and Dehelly, and the fact that the blood went directly from arm to arm gave it an acknowledged superiority over all of the ancient methods, in which defibrinated blood was used. But the objections to the direct method of transfusion were numerous, and its field became much restricted in consequence. Passing by the venovenous direct methods, we come to the Kimpton apparatus, in which the blood was made to pass into a glass vessel before entering the recipient; this step made it possible to prevent coagulation and to measure the volume of injected blood.

The apparatus of Jeanbrau is, in brief, this apparatus of Kimpton's, with slight modifications. The technique, however, is individualized. The first step consists in aspirating into the ampoule 25 c. c. of sterile solution of sodium citrate. The median basilic vein of the donor is then punctured under cocaine, and the cannula introduced; when under the influence of aspiration produced by a bellows apparatus, the blood enters the ampoule under pressure. The vein of the recipient is now opened—the cephalic is preferred—the ampoule is connected, and the blood is allowed to enter the recipient very slowly, by the operation of a bulb.

The objections urged against this mode of transfusion appear to be theoretical only. At least, no case of air embolism or contamination with disease is mentioned in this paper. Naturally, systematic precautions have been taken. A death from anaphylaxis is mentioned, but the particulars are not given; apparently the donor had just received antitetanic serum. Such a donor is, of course, prohibited by the routine precautions.

SURGEON PROBATIONERS IN THE BRITISH NAVY.

The arrangements that are found necessary in order to keep supplied the medical services in the British army and navy make rather an interesting study in social economics. In the earlier days of the war the military authorities allowed the senior students to remain at their classes while they called up the students who were at a less advanced stage of their studies, if they were physically fit. At that time, doubtless, it was the belief of the military experts that only the senior students would be at all likely to be available as qualified medical men before the war was brought to a close. Unexpected events have shown that too sanguine a view had been taken of the situation, and during last year it became evident that a rearrangement was urgently required. The senior students had now qualified, and were swept into the army as medical officers, but clearly the supply of young qualified men could not continue, as their juniors were already in the service as combatants; yet there was every indication that hostilities were likely to be prolonged. Under these circumstances the authorities have released all junior medical students so that they may resume their studies and help to keep up the supply of medical men so urgently needed.

In the navy, on the other hand, medical students

have been doing exceedingly useful work in the smaller vessels attached to the fleet. The surgeon probationers, as they are called, attend to casualties occurring on their vessel until these can be transferred to a hospital ship or to a hospital on shore. They thus economize the services of the regular surgeon, and do a great deal to relieve the strain on the medical service. That the services of these surgeon probationers have been recognized and valued by the navy is evidenced by the references to their work in dispatches. Like their comrades in the army, the surgeon probationers are now being released to resume their studies, and in order that their places may be filled the naval authorities have invited application for these posts from students in their third year who have already passed the second professional examination or hope to do so soon.

Dental Stigmata of Syphilis.

Syphilographers, such as Fournier, Gaucher, Sabouraud, and Hutchinson, have erected an extensive superstructure of dental dystrophies of hereditary syphilitic origin which include total and partial microdontism, anomalies of position, monstrosities, alterations of shape, alterations of mastication zone, spaced incisors, Carabelli's tubercle, etc. Roy, in a recent number of a dental journal (abstracted in *La Presse Médicale*, May 16), is antagonistic to the whole of this teaching. Not a single stigma, not even Hutchinson's teeth, he holds, is pathognomonic of hereditary syphilis. Any disease of the early period of childhood can provoke dystrophies of the teeth. Caries of the deciduous teeth is a powerful factor in retarding development and causing errors of implantation, because this affection influences the development of the jaws. Mouth breathing, however produced, likewise exerts a retarding influence on the development of the dental arches, and is thus a cause of malposition. Erosion of the free border of the incisors, causing the so-called notched teeth of Hutchinson, means simply, in Roy's opinion, that the infant suffered from some serious pathological state in the first three months of life. It could be syphilis, but it could also be measles or bronchopneumonia. The notched incisors do not develop in the heredosyphilitic child unless there has been a period of grave infection corresponding to the first three months of existence. These dystrophies show absolutely no peculiarities in the syphilitic infant.

Fatal Lethargy of Encephalic Type.

In 1890, cases were reported in upper Italy, Hungary, and Dalmatia of a fatal type of lethargy. Owing to the lack of exact information, no true idea of the malady was obtained, and it became a mere legend. Last year a similar affection appeared in Vienna, and, more recently, cases have been reported in Paris, London, Sheffield, and Manchester. In Vienna, where the affection prevailed very widely, it suggested a form of poliencephalitis, which was not related to infantile paralysis. One author claimed to have inoculated a monkey successfully with the disease products and to have isolated a pathogenic coccus. In Paris, some 71 cases are known to have occurred, 15 of which were seen by Netter, who brought up the subject in the Academy of Medicine last May (*La Presse Médicale*, May 9). The mortality was 50 per cent. or more. The victims were seized in the midst of health with fever, headache, and prostration, and soon became somnolent, and in fatal cases comatose. Very characteristic were the ocular symptoms, which were usually bilateral. These included ptosis, strabismus, nystagmus, and pupillary alterations. The muscles innervated by the facial sometimes participated. The symptoms of meningitis were absent, or only faintly suggested. In fatal cases death at times supervened rapidly, while in the cases of recovery the affection sometimes persisted for months with protracted convalescence. Fatigue and ocular disturbances were often persistent. Lumbar puncture was practically negative. The autopsy finds in the nervous centers were but little in evidence to the naked eye. To the microscope the nerve cells of the cortex were but slightly modified, alterations being largely limited to the region of the motor muscles of the nerves supplying the eye in the bulb, protuberance, and gray matter of the wall of the ventricle. One cannot see in the symptoms any evidence of food intoxication, and the phenomena of botulism show notable differences, such as the prominence of mydriasis and dryness of the mouth. Encephalitis is the exception in botulism. There is every reason to see in this lethargic malady an independent affection which can be propagated by carriers.

News of the Week.

Cholera Spreading in Russia.—An epidemic of cholera, centering in Petrograd, where 500 persons are reported to be dying daily, is spreading over European Russia and threatens to cross the border into Germany. It is said that there are thousands of persons suffering from cholera at Saratov and many more in Finland. Advices from Stockholm announce that the Swedish capitol is in the throes of a cholera scare. A quarantine has been established against vessels coming from Petrograd. The disease has also broken out in Moscow, where 224 cases were reported on Sunday.

Tuberculosis More Deadly Than Bullets.—In connection with the campaign against tuberculosis which is being launched by the National Tuberculosis Association, Dr. Livingston Farrand, Director of the American Commission for the prevention of tuberculosis in France, states that statistics covering the four years since the start of the European war have disclosed that the mortality from tuberculosis among the civilian population of the countries engaged in hostilities is at least as great as the total number of soldiers killed in battle. Among the men called to the colors under the first draft 50,000 were found to be tuberculous. Dr. Farrand points out that such a finding as this warrants an appeal for the support of an energetic renewal of the fight against tuberculosis.

Asks Senate for National Drug Commission.—A measure has been introduced into the Senate, known as the Frelinghuysen Drug Resolution, which authorizes the President of the United States to appoint a commission of citizens of the United States, not exceeding three in number, to

make inquiry into the subject of narcotic and habit-forming drugs. This resolution carries with it an appropriation of $50,000 for the prosecution of this work. It was introduced into Congress after a study of facts brought out during a recent survey of several States made by Dr. Charles A. Rosewater of Newark, which went to show that the use of narcotic and habit-forming drugs in the form of opium, morphine, heroine, and cocaine, is largely on the increase.

Labor League Includes Health Measures in Political Platform.—The Labor League of New York City, in preparing a program defining its stand in the coming fall campaign, states that it favors the establishment of state-administered health insurance and the creation of a Bureau of Sickness Prevention and Health Promotion within the State Labor Departments. It calls for the erection and maintenance of a tuberculosis sanatorium in each county, with county management and State supervision. It also advocates old age pensions for citizens who at sixty years of age are without incomes and have been residents of the State for twenty-five years.

Child Health Organization.—Some time ago a group of specialists in diseases of children met in the New York Academy of Medicine and organized a Committee on the War Problems of Childhood. A few weeks' study showed that the wartime problem as related to children was so broad that a larger organization was desirable. The matter was referred to Secretary Lane of the Department of the Interior who urged the formation of a National Committee. However, as it seemed undesirable to add an entirely new organization to the many already in existence, it was decided to affiliate with the National Child Labor Committee, hence the Child Health Organization has come into existence. Its proposed lines of activity are to teach health habits to children and to secure adequate health examinations for all children in the public schools of the country; to consider the urgent problem of malnutrition among school children; to safeguard the health of children in industry; to awaken the public to the necessity of conserving the health of the school child as a basis of national security and stability; to promote or cooperate with other bodies in securing legislation for the attainment of these objects. Dr. L. Emmett Holt is chairman of the executive committee. Other physicians on the executive committee are Dr. Samuel McC. Hamill, Dr. Godfrey R. Pisek, Dr. Victor G. Heiser, Dr. Bernard Sachs, and Dr. Thomas Wood.

Automobile Accidents Increase.—The National Highways Protective Association finds that in June, 1918, the accidents for New York State, including New York City, were 99, as against 72 for the same period of 1917. In New York City, in 1918, motor cars killed 57 persons; wagons, 11; trolley cars, 6. During the same period of the previous year there were killed by motor cars, 33; wagons, 7; trolley cars, 9. In New Jersey motor cars killed 83 in the first six months of this year, as compared with 100 during a similar period of 1917. Massachusetts and Connecticut also show a corresponding decrease. The New York Health Department, in commenting on these figures, emphasizes the need for more radical legislation in the operation of motor vehicles or more stringent enforcement of our present laws.

Public Health Service Urges Care in Reporting Communicable Diseases.—The United States Public Health Service has sent a letter to all local health officers stating that it is important for the health of the troops in camps that every community, no matter how small, report the presence of all communicable diseases, especially if present in epidemic proportions. It is pointed out that selected and enlisted men in traveling may be exposed to such diseases and carry them to camp. Local health authorities are reminded of the grave responsibility that rests upon them of obtaining reports of all notifiable diseases from the doctors in their jurisdictions. The attention of all physicians is called to the importance of reporting communicable disease immediately and that all instances in which enlisted or selected men have been exposed to such diseases be reported immediately. The plan of action suggested is as follows: (1) The physician should make an immediate report to the local health authorities, who should notify (by telephone or telegraph if necessary) the senior medical officer of the camp or post to which the selected man or soldier may become a menace. A duplicate notification should be made by the local authorities to the State health authorities. (2) If there be no local health authority having jurisdiction, the physician should notify (by telephone or telegraph if necessary) the State health officer, who should notify (by telephone or telegraph if necessary) the senior medical officer of the camp or post to which the selected man or soldier is about to go. (3) The notification should be explicit, giving name of selected man or soldier and other identification data, together with his address and the nature of the disease. (4) The notification of the senior medical officer of the camp or post by the local or State health authorities should be in addition to the present procedure in such cases.

New York Babies Underfed.—The Mayor's Committee of Women on National Defense, after a careful investigation with reference to children between the ages of two and six years of age, finds that 21 per cent. are underfed. The Committee will cooperate with the Bureau of Child Hygiene of the Health Department to distribute free milk at the fifty-nine stations already established for infants to children of pre-school age.

Dr. Abraham Jacobi, who fought for freedom in the uprising in Germany in 1848, has accepted the place of honorary president of the Friends of German Democracy, an organization mostly of Americans of German descent who favor the destruction of Hohenzollern rule in Germany.

Dr. William S. Thayer, formerly of Baltimore, who was made a Colonel of the American Expeditionary Forces in France, on June 18, has been elected a foreign member of the Paris Academy of Medicine.

Gifts and Bequests.—Among the bequests made under the will of the late John W. Sterling is one of $7,500 to the Presbyterian Hospital of New York City and one of $10,000 to the Bridgeport Hospital, Bridgeport, Conn.

Epidemic in Porto Rico.—Ten thousand persons in San Juan have been ill of a three-day fever during the past two weeks. In some places business houses have been forced to close because of illness among employees.

Health Department Wants Bureau of Oral Hygiene.—A resolution has been presented to the Board of Aldermen of New York City which proposes to amend the Sanitary Code so as to provide for a Bureau of Dental Hygiene in the Division of Child Hygiene. Dr. S. Josephine Baker in urging the adoption of this measure states that of all the pupils in the schools of the city 67 per cent. have been found on inspection by the department inspectors to have defective teeth.

Drive for Bowling Green Neighborhood Association.—The Bowling Green Neighborhood Association which has tried to better conditions in that part of Manhattan south of Vesey and Ann streets has begun a drive for $30,000. This organization established the first health center in the United States and has reduced its death rate for babies in that district from 321 to 175 per thousand, and it also conducts social welfare work along various other lines.

Obituary Notes.—Major Morris Jacob Karpas, M.R.C., U. S. A., died in France last week, at the age of 38 years. Previous to his entrance into the army Dr. Karpas was a practising physician in New York City, being a graduate of the Long Island Hospital Medical School in 1904. He was chief of clinic at the Neurological Institute and adjunct neurologist at the Montefiore Home, and was a member of the N. Y. Academy of Medicine, of the New York State and County Societies, of the American Medical Association, and of several psychiatric and neurological societies.

Captain Paul Clements, formerly of Nashville, Tenn., died in Chinese waters, on June 29. He was a graduate of Vanderbilt University Medical Department, Nashville, Tenn., in 1895. In the beginning of the Spanish American War he enlisted in the First Tennessee. He was sent to the Philippines and remained there in charge of the Culion leper colony until the present war.

Dr. Gottfried Merckel of New York, a graduate of Long Island College Hospital Medical College, in 1907, died as the result of injuries received in an accident on July 16. He was 43 years of age.

Dr. C. Lanier Carter, a graduate of the University College of Medicine, Richmond, Va., in 1903, died at his home in Danville, Va., on July 10, aged 41 years.

Dr. Alfred Drury, of New Brunswick, N. J., a graduate of the New York Homeopathic Medical College and Hospital, in 1900, died at Ocean Grove, on July 10, aged 46 years.

Dr. John L. N. Hunt, a retired physician, died at the residence of his son, in Flushing, L. I., on July 18, aged 80 years.

Dr. William Karniol, a graduate of the University and Bellevue Hospital Medical College, in 1902, died at his home in this city on July 15.

Dr. Frederick R. Marvin of Albany, N. Y., died on July 22, after a long illness. He was born in Troy in 1847, and was a graduate of the College of Physicians and Surgeons, New York City, later entering the Congregational ministry.

OUR LONDON LETTER.

(From Our Own Correspondent.)

EXPENSIVE DRUGS FOR PANEL PATIENTS—A SPECIAL DENTAL TRIBUNAL—MEDICAL EXAMINATION AND THE GRADING OF RECRUITS—DEATH OF PROFESSOR H. G. PLIMMER—TUBERCULOSIS AND ANTITYPHOID VACCINATION—CASUALTIES IN BOMBING RAIDS ON HOSPITALS.

London, June 27, 1918.

How often the premonitions of those who at the time of the passage of the National Insurance Act were critical concerning the fair working of the panel scheme have come true in the event! While to the country and to the medical profession the practical outcome of the Act has been good, many difficulties attendant upon the working of the panel scheme have been realized, and they are those which were anticipated. Panel practice was only in the infancy of its working when the war broke out, but already it had been found that a certain number of practitioners were admitting to their lists more patients than they could fairly expect to treat in an adequate manner, with the result that in their panel practices they were reproducing many of the ills formerly associated with the out-patient departments of general and special hospitals. This was hardly to keep the promise by which the passing of the Act was secured, viz., that every insured person should receive the best of medical attention from the doctor of his choice. Further, in connection with many practices doubt soon arose whether the medical material supplied in response to the prescriptions of panel practitioners was of first-class quality or whether the more expensive drugs would not be denied to many panel patients who, before the passage of the Act had received through the charitable offices of hospitals the best pharmaceutical products. Under the National Insurance Act (Medical Benefit Regulations) the supply of drugs is in ordinary circumstances expected to come from pharmaceutical chemists who in return for capitation fees dispense the prescription of the panel practitioners. But pharmaceutical chemists are limited in number nor can they live by the practice of pharmacy. Therefore, and of necessity, they reside in localities where the population creates a demand for other things than drugs. Hence in many rural communities the nearest pharmaceutical chemist is far distant from many of the patients, and in these circumstances the National Insurance Act permitted the practitioner attending an insured person to arrange for the supply of drugs when the nearest druggist lived at an inconvenient distance. The practitioner had to be willing to undertake the extra work and responsibility, as no compulsion could be put upon him in regard to his professional duties, but when such an arrangement was made the practitioner could be paid by capitation fees calculated with respect to the number of persons toward whom he had assumed liability. But such an arrangement would have no restriction as to the nature or cost of the drugs actually supplied, and it might mean that where the practitioner was generous he would lose money, and where he was over careful in his own interests the patient would lose his chance of

the best pharmaceutical remedies. That this difficulty might arise was foreseen long ago. Recently a medical man having found an insured patient suffering from tetanus obtained antitetanic serum for him at considerable cost and applied to the National Insurance Commissioners for reimbursement. He had contracted to supply drugs to those of his insured patients who lived more than a mile from the druggist, as did the patient in question, and to do so on a capitation basis; but it was contended for him by the London and Counties Medical Protection Society that antitetanic serum was not a drug within the terms of his contract. Certainly antitetanic serum, being adjudged the best remedy in the circumstances, was due to the insured patient, who had been promised in Parliament that he would receive under the Act the best available treatment; but while the National Insurance Commissioners were bound in such circumstances to supply the remedy, it was not fair, contended the Protection Society, that the pecuniary onus should be placed upon the practitioner, because he had assumed a liability for the supply of drugs of ordinary character. The representations of the Protection Society proved unavailing, and there seems no doubt that under the Act the medical man was bound to pay for the antitetanic serum, and could not be reimbursed by the Commissioners. But, as publicity has been given to the case, in future we may expect practitioners who are willing to accept the general responsibility of supplying their insured patients with drugs (a pharmaceutic chemist not being accessible) to guard themselves against extraordinary liabilities for medical material.

It has now been definitely settled that a registered dentist shall not be called for military service except for dental work as a commissioned officer. The position of registered dentists becomes similar to that of medical practitioners, and to deal with the best distribution of the dental practitioners of the country between civil and military employment a Special Dental Tribunal has been appointed, with Dr. G. Seaton Buchanan, C. B., Chief Assistant Medical Officer to the Local Government Board as chairman. To this Board all applications for exemption from military service *as dentists* will now be made.

As I have indicated in previous letters the medical examinations and grading of recruits, under the latest extension of the conscription age, proceeded at first quite smoothly. The substitution of what are practically civilian boards—though recently retired medical officers in the Army and Navy may find their places upon them—for Medical Boards composed largely of Service men, led to a more fair and efficient categorizing of the material than the recruits in the earlier stages of the war had received. The work of the boards, when carried on by those in daily experience of the disabilities of male civilian manhood in every class between the ages in question, was more rapid and more to the point, while the fact that those men who were not required for military service might be relegated to civilian duties under the Ministry of National Service, removed in the case of persons of doubtful physique the disagreeable feeling that, with them, it was everything or nothing. There was, and is, however, a very large population to be considered. Mistakes were inevitable, critics numerous, and, as always happens, the errors soon began to receive a publicity which had never been granted to the early success of the new scheme. Wherever a man had been wrongly graded he was sure of warm sympathy, and no obstacle was put in the way of the ventilation of his case either by letters to the newspapers or by questions in Parliament, so that by the middle of June a fairly steady stream of detraction began to flow in the direction of those responsible for the grading of recruits. Sir Auckland Geddes, the Minister for National Service, made many reasonable, and some not quite intelligible, replies to hostile interrogatories in the House of Commons; and, while he has thus removed the impression, that might have been derived from the complaints, that the whole recruiting system was a failure—and one attended, moreover, with a train of private tragedies—he did not convince the House of Commons, or the public that at certain of the Boards the examinations had not been made with undue haste, while he had to admit that in one case an official circular letter of instructions, which was withdrawn almost as soon as it was issued, contained possibilities for great mischief. What lies behind the whole thing is the belief, not quite ungrounded, that the grading of the Recruiting Boards, designed to keep certain men away from subjection to physical strains which they could hardly be expected to meet, may later be disregarded by the military authorities; and it is difficult to see how this contingency can be avoided. As a matter of fact, the only thing any Medical Boards can fairly do is to settle what a man's physique is, judging, also, by physical signs whether he is reasonably fit for his age. It may not be possible for a doctor to place a man absolutely in a pigeon hole, but his possibilities can be gauged. Now it is stated that over and over again there have been posted to battalions, having had their categories altered by the military medical officers, men who had been considered by the Medical Boards as unfit for such work. This is a far more serious suggestion than the suggestion that certain successful appeals from the conclusions of the Medical Boards prove the work of those Boards to be ignorant or perfunctory. The medical view of the situation, which is admittedly one of difficulty, is that the work under the Ministry of National Service is being well carried on. The public distinctly desire that the medical grading should be done by the medical men of the country and not by the military authorities. This has been granted. The medical men of the country have clearly nothing to gain by the responsibility which is now theirs, for the work on the Recruiting Boards is hard and poorly paid. It is admitted that the majority of the complaints have been met with ready explanation; but concerning those which have been well founded, the serious question arises whether an avoidable evil exists, or whether we are only dealing with that margin of error which is inevitable in big human undertakings; for, after all, the question of a man's fitness is a matter of opinion. When, however, the Medical Boards have come to an opinion, it is not for military authorities to revise that opinion.

Professor Henry George Plimmer, one of the most learned English pathologists, has died this week in the house of his friend, Mr. Robert Mond. Plim-

mer, who was formerly bacteriologist and lecturer on pathology at St. Mary's Hospital, London, became in the first place well known for his microscopical work in connection with new growths, and he was at one time credited by many with having solved the question of the causation of cancer by the discovery of certain low organisms, called "Plimmer's bodies," in association with malignant tumors. Plimmer himself repudiated a claim which he later found could not be supported; his work, however, was not wasted, as he closed a fruitless patter of investigation that would have proved inviting to other researchers: Plimmer's next post was that of pathologist to the Royal Zoological Society, and while thus occupied he was elected F. R. S., as well as President of the Microscopical Society. Lastly he was appointed Professor of Comparative Pathology in the Imperial College of Science, and at the time of his death was working there regularly with his old friend, the Rector of the college, Sir Alfred Keogh, who returned to his civilian post on retirement from the position of Director General of the Army Medical Service.

The enemies of scientific medicine have certainly not been voiceless in Great Britain since the war broke out. They have had in journalistic slang "a good press." Their numbers, never very large, have not increased, but they are over represented in Parliament and make a sensational appearance in the lay newspapers. These are the people who have deeply resented the protection, practically complete, of the British Army from typhoid fever by inoculation, and recently one of them attempted in Parliament to have it admitted that the incidence of tuberculosis bore relation to antityphoid inoculation and vaccination! This wise senator asked the Minister of State for War whether his medical advisors would inquire into this relation, evidently believing that it was a point that had escaped attention. To his mortification, however, the Assistant Secretary was able to answer that a special investigation had been made into this matter, when particular attention was directed to the possible influence of inoculation and vaccination upon tuberculosis. The result of the investigation, said the Assistant Secretary, showed the inoculations and vaccinations at present carried out to have no effect whatever of the nature suggested. All medical men will be pleased that the War Office should have got this opportunity, unwittingly offered them, of championing the cause of scientific medicine, but experience tells us that nothing is ever gained as far as the particular cranks are concerned by telling them the truth. The same people ask the same questions weekly, almost daily. They are punctually, and, as a rule, courteously, assured that the inuendoes against scientific medicine concealed in the questions have no foundation whatever; but, fanatically believing that there is a conspiracy against them, they repeat their interrogatories "in the cause of humanity." For these people the cause of humanity means the sacrifice of any amount of life rather than the countenance of any modern scientific medical treatment, and, owing to their persistence, they get support they do not deserve.

At the end of May and the beginning of June a large hospital area in France was bombed on no less than seven occasions, a fact which to some extent accounts for the sad increase in the fatal casualties among the officers of the various medical services. The total casualties in these seven air raids, which include the casualties in the hospitals, have been given as follows:

	Killed	Wounded
Officers	11	18
Other ranks	218	534
Sisters	5	11
Q. M. A. A. Corps	8	7
Civilians	6	23
	248	593
		248

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

REFUGEES SUCCORED BY THE RED CROSS—COOPERATIVE STORES FOR THE SOLDIERS—ADOPTING THE FRENCH WAR ORPHANS.

PARIS, June 11, 1918.

THE American Red Cross took care of thousands of refugees hurriedly evacuated from the war-swept Somme region. Hastened from their homes, some of them at only a few hours' notice, they were able to bring with them little more than bare necessities. Burdened with the care of little children and many of them with babies in arms, they were fed and lodged until trains could be provided to remove them from the city. Then it was in American Red Cross "camions" that they were taken either to other stations, or, in the case of the more fortunate ones, to homes of relatives in Paris. Every train brought in its contingents of refugees—homeless old men and women and wondering children—and by the hundreds, they were led, for they seemed to have so little of their own wills left, to the canteen in the basement of the station, where hot food and drinks were waiting for them. The utmost efforts had made it possible to be ready to care for these thousands as they trooped from the trains, whatever the hour of day or night. Those who arrived on the late trains were provided with beds in the main room of the canteen, where they were first served with hot suppers.

The first contingent to reach Paris numbered 300 persons, who had been prisoners in German hands for three years, until the enemy was forced out of the region last spring. They had been ordered out of their homes at seven o'clock last Sunday night and had been allowed until midnight to gather their belongings into slender packages and reach the train which was to bring them to Paris. It was in this evacuation that the American Red Cross began its work by collecting these unfortunate people and carrying them and their pathetically small bundles to railway stations. The bundles were eloquent of the haste with which they had made their journey, to what destination their owners had no idea beyond that they were first going to Paris.

How to enable American soldiers to buy such things as may be required or thought necessary, from time to time, has been discussed by many persons solicitous for the welfare of the troops; if it were to be accomplished by private or public coopera-

tive companies, the project would be too vast. But the military authorities or the Government could accomplish this, and, in fact, it has been done in France since the beginning of the war. In France the military authorities selected experts who were known to be the right people to conduct such a great enterprise, and these men were taken from the mobilized business men. Without doubt the success of the French cooperative societies served as a model for the army cooperative administration. All the immediate necessities of life are attended to by the Intendance of the army; but there are many things supplementary to these essentials, such as luxuries or comforts not contemplated by the ordinary army administration. Here the military cooperative system has accomplished good results. The ordinary existing cooperative societies in France cannot, of course, go to the front. The cooperative organization is quite complete in the French army. For each army there is a store for purchasing foods, which store is supplied in large quantities by big contractors. Generally, business men who are in the army are selected for buying in wholesale quantities. Every division has its cooperative store, which is to be found at the front and at other places as occasion requires.

In cooperation with the soldiers' paper, the *Stars and Stripes*, the American Red Cross has agreed to carry out that paper's scheme for the adoption of French war orphans and the children of families rendered destitute by the war. The scheme provides for a unit of soldiers to undertake the care of a child, contributing Fcs. 500 yearly toward its support. All money contributed will go to pay for the education of the child, the Red Cross paying the expenses of administering the funds paid by the soldiers. Photographs and the history of each child adopted will be furnished to its foster parents, and monthly reports will be made by the American Red Cross of the ward's condition and surroundings. It is hoped to use part of the funds in sending the older children to agricultural and trade schools.

2. The Mentally Defective Criminal. Amos T. Baker.
3. Treatment of Colds. D. C. Dennett.

3. Treatment of Colds.—D. C. Dennett makes a plea for the early, careful treatment of colds, which are the first stages of pneumonia, pulmonary tuberculosis, many cases of so-called rheumatic fever, and other serious diseases. That is, the germs of these diseases first exist on the upper mucous membranes, and, therefore, the best prophylactic is sterilization of membranes, plus rest and hygienic environment. A cold is a localized disease at first and in the first twenty-four hours may be treated as successfully as a specific urethritis in the same stage. In view of the importance of prompt treatment, orders in military camps should require colds to be reported when the first symptoms appear. Proper local treatment is essential, especially of the triangular area the apex of which is on the posterior pharyngeal wall opposite the tip of the uvula, the base up, with the two upper angles marked by the openings of the Eustachian tubes, called by the writer the "triangle of fire." A cold may remain localized for a week, without subjective symptoms, as in the case of the "carrier." Treatment should first be carried out in the eye—a 50 per cent. solut.on of silver vitellin should be applied to the everted lids, a tube of White's ointment being kept for use in case of smarting of the eye. Patient should also be given a 25 per cent. solution for use in the eyes and nose. The author adds: Do not poke a cold with medicated cotton on a stick; do not spray a cold; do not give aspirin except for pain, and do not give quinine and whiskey, but treat a cold seriously because it is a serious disease. Give sulphate of atropine and aconite in the first stage of "head colds," steam and oil inhalations and warm air for "loss of voice colds," and Dover's powder early for "cold on the chest." The present paper is based on the treatment of over two thousand cases with 25 per cent. to 50 per cent. solutions of silver and argyrol applied locally, combined with internal medication to suit the case. If used at the right time, local treatment is the most effective.

6. A Survey of Ear Conditions in Young Children.—E. Willis Kobler has examined the ears of 500 school children in New York City and his observations have led him to the conclusion that discharge from the ears of young school children is more prevalent than is usually supposed. He points out that this is of vast importance as bearing on acuteness of hearing in later school life. The number of cases of impaired hearing in later school life, however, is relatively small, which may be explained by the fact that in many cases corrective treatment has been instituted and tonsils and adenoids removed. Many cases of defective hearing do exist nevertheless, and may be accounted for by the neglect and refusal of parents to remedy defects, deformity of the nasal septum which cannot be corrected in early age, abnormal collection and deposit of cerumen coupled with uncleanliness, catarrhal conditions of the nasopharynx with incomplete and insufficient instruction in nasal and oral hygiene, and the lack of adequate instruction in aural hygiene. Home remedies and adjuncts for earache are also frequently harmful. The author believes therefore that a special extended survey and examination of the ears of school children should be made with reference to the conditions mentioned.

1. Surgery of the Gall Bladder and Biliary Ducts.—E. Starr Judd. (See MEDICAL RECORD, June 29, 1918, p. 1143.)

2. Indurative or Rheumatic Headache.—Hugh T. Patrick points out that rheumatic or indurative headache, though not common, is far from rare. A knowledge of its symptoms is worth while as it may be mistaken for serious intracranial disease or for an unimportant functional headache, and because if not correctly treated it may continue for months and years, while proper treatment practically always cures it. It may be acute, but is usually subacute or chronic, is most frequently met with in patients over 40 years of age, and more often in women than men, in the proportion of four to three. The pain may be intense or merely nagging, and is steady with remissions and exacerbations. In the acute cases the pain never ceases but fluctuates; in subacute cases complete intermissions are few and short, remissions are longer but rarely for more than a few days. On the whole the pain is apt to be worse in the afternoons and evenings. Nausea and vomiting are not present. The pain is usually occipital or suboccipital and may radiate to the vertex, the frontal or the temporal areas: it is never frontal or vertical alone, and rarely temporal. It is more often bilateral than unilateral, and though the patient speaks of it as headache, it is almost confined to the back of the neck with radiations upward, and for this reason the writer has labeled the cases "arthritic headache." Tenderness to deep pressure is present, especially in the lower occiput and lower neck. Other evidences of so-called rheumatism are also present, such as pain on movement of the neck and, sometimes, in the spinal joint, shoulder, hip, and even the smaller joints. The headache is worse after exposure and is aggravated by physical exertion and frequently by mental application. Patrick believes the condition to be due to infection usually from some focus in the head—the throat, teeth, ear, sinus, or suppurative rhinitis, though a study of the literature throws little light on this. He attaches no importance to the theory, put forth by the masseurs and widely accepted, that the cause of the condition is to be found in nodes or strands, and points out that these nodes are found in normal people and frequently absent in persons suffering from rheumatic headache. It is to be noted that in acute cases fever and leucocytosis are always present; in chronic cases they are frequently absent, though repeated examinations, especially during exacerbations of pain, as a rule will show a temperature of 99° to 100° F. and a white count of from 8,600 to 9,000 or 10,000. The rational treatment is to find the focus of infection and remove it. Subacute cases should be treated by rest, heat, and massage. In chronic cases repeated and prolonged applications of heat followed by persistent massage for an hour or more are indicated. The massage must be firm and deep and must be repeated about three times a week for many weeks. The thermocautery may sometimes be used with benefit.

1. The Goulstonian Lectures on Modern Views on Diabetes and on the Significance of Acidosis in Disease: Lecture I.—E. P. Poulton reviews the history of the treatment of diabetes by fasting, showing that this is not new. He points out that Allen was the first to define the principle that the diabetic must be permanently underfed, thus indicating the way in which the return of sugar could be prevented. Treatment by fasting has been carried out by Poulton in cooperation with Dr. J. H. Ryffel at Guy's Hospital. It is impossible, of course, to follow the history of all hospital cases, but figures are given to show that the mortality in hospital was only 7.7 per cent. in cases treated by this method since 1916, as compared with a mortality of 23 per cent. in the preceding ten years, and 17 per cent. in Pavy's cases, 1883-1888. Of 49 cases, 36, or 73.5 per cent., were sugar free at some time, and 30 were sugar free for long periods at a time. Seven cases in the septic wards all became sugar free for varying periods. It was found that the treatment by fasting and the subsequent addition of food in small quantities was by far the most successful way of treating diabetes; and there was, moreover, evidence that the life of the patient was prolonged. The advantages of this treatment are that the patient is rapidly made sugar free; it is quickly seen whether the treatment will be successful or not; no medicines or diabetic foods are required; the patient can be taught to test his own urine, and definite rules can be laid down by which he can regulate his own diet. This treatment is not a cure for diabetes. The tolerance for carbohydrate in a severe case does not increase with the treatment; in fact, it may diminish in spite of it, if the disease spontaneously progresses. As for the cause of the success of the treatment, Poulton adopts the view that the tissues of the body, to a large extent, have lost the power of utilizing sugar, and that the hyperglycemia is a secondary result. The explanation of the disappearance of the glycosuria is that the carbohydrate store is largely used up at the beginning of the starvation period, and so there is less drain on the body proteins. Poulton next considers the effect of fasting upon acidosis. It is generally accepted that aceto-acetic and β-oxybutyric acid arise from fat. The explanation of why these are formed to any large extent only when carbohydrate is not available in the organism and the means whereby they are formed have led to much discussion. In regard to Hurtley's view that aceto-acetic acid is formed under normal conditions, but that it is almost entirely katabolized, Poulton points out that the normal person metabolizes both fat and protein in large quantity and that there need not be very much increase in this metabolism after carbohydrate is withdrawn from the diet. Also there must be some qualitative difference in the protein and fat metabolism when ketosis occurs. He further suggests that there is a call for carbohydrate on the part of the organism and this comes from fat, with the simultaneous formation of acid bodies, when no carbohydrate is available. It may be objected that the formation of sugar from fat in diabetes is a much debated point, American workers being absolutely against it, believing sugar to be derived from protein or carbohydrate. The main argument, however, against the view of the conversion of fat into carbohydrate is provided by the D to N ratio. Finally, Pembrey's experiments on hibernating animals are conclusive as to the power of the animal body to make this conversion. Geyelin and Du Bois have shown that as a result of fasting in diabetes there is a rise in the respiratory quotient, accompanied by (1) lessening of acidosis; (2) diminution in the respiratory exchange; (3) lessened sugar and nitrogen output; (4) lowering of the D/N ratio. These facts can be explained only by the assumption that fat is converted into sugar. The lecturer also points out that patients given the treatment under consideration seem to reach a point of equilibrium on a diet, the caloric value of which is lower than that usually regarded as essential for a man taking active exercise. This question has been investigated by Joffe, Ryffel and Poulton, who conclude that patients with diabetes can live on a diet of low caloric value and yet keep their weight constant, because their resting metabolism is permanently reduced, and that it is this lowered metabolism that is the secret of the success obtained by the fasting treatment.

6. Intestinal Obstruction Due to Diaphragmatic Hernia. Captain L. S. Dickie.

1. An Address on the Significance of Cardiac Murmurs.—Claude Wilson reviews the nature and significance of cardiac murmurs. He lays particular emphasis upon the necessity of considering each case as a whole, estimating the presence or absence of definite signs of cardiac embarrassment, and giving due consideration to the heart's response to effort and more especially its capacity to meet the ordinary—and extraordinary—strains of life. Thus he says: "On no solitary sign shall any heart be condemned." He points out that many of the functional and physiological murmurs so commonly found, especially in the young, are negligible when found in conjunction with a good cardiac response to effort, citing a number of cases which go to prove this. Systolic murmurs resulting from endocarditis are more serious because they are apt to be permanent, to become associated with other murmurs which are not systolic, to be accompanied by vegetations, and because both in pericarditis and endocarditis the myocardium is very likely to be invaded, and the heart muscle damaged, perhaps permanently. Organic disease may be assumed as the rule when cardiac signs and symptoms develop in the course of rheumatic fever, and caution is then, of course, necessary during convalescence. Later on diastolic murmurs may develop or the missed beats of partial heart block may be noted. Should recovery of myocardial tone take place, carefully graduated exercise should be permitted. The condition of the heart muscle is the all-important factor in such cases. It is, moreover, necessary to ascertain whether auricular fibrillation is present, in which case, he points out, the pulse presents an absolute irregularity, no two consecutive beats being the same in time or volume. Many cases of cardiac enfeeblement occur in which a systolic murmur is the only audible sign, but there is always evidence of weakened muscle and often of auricular fibrillation. The outlook in these cases is always menacing and it is probably this association that has invested the mitral systolic murmur with its halo of sinister augury. The signs and symptoms have been attributed to "back pressure" but in reality are due to impairment of the cardiac mechanism consequent on disease of the muscular wall and failure of the auricles to contract; if there is any back pressure at all, it is a minor factor, and proceeds, apart from extreme narrowing of the mitral orifice, equally and simultaneously from both sides of the heart. Although no convincing explanation has yet been offered as to why systolic murmurs are often negligible, Wilson suggests that a consideration of the lesions that give rise to them, and of the effects which are likely to result on the cardiac mechanism and on the heart's nutrition, affords an explanation. On the right side a tricuspid systolic murmur is known to be often physiological and that the regurgitation is generally inconsiderable is shown by the small size of the ventricular wave in the jugular tracing. It is probable that a similar state of things is common also at the mitral valve, while even a more considerable backwave is not serious in an otherwise healthy heart. In the cycle of events the left auricle contracts, and throws its blood into the ventricle, and then immediately dilates and begins to fill again from the large veins, which are not only full of blood ready to pour into it, but must also be actively aspirated by the intrathoracic pressure being lower than the atmospheric. When the ventricle contracts the blood is driven in the direction of least resistance—into the open aorta—and any that regurgitates through the mitral valve is met by the contents of the auricle. Very little will get through for even if the mitral dilatation is considerable the counteracting forces are far from negligible. Moreover, the period during which regurgitation is possible is limited to the duration of the ventricular systole. This is perhaps the main point, for the reserve power of the heart is enormous and depends essentially on an unrestricted blood supply to the myocardium. In stenosis which is due to adhesion of the margins of the cusps, slight narrowing may give rise to a loud murmur; if there is much stenosis there is also incompetence, and we may be pretty sure that if there is no diastolic murmur the narrowing does not amount to much. In the case of disastolic murmurs, the lesions which give rise to them (mitral stenosis and aortic incompetence) produce effects which hamper the mechanical action of the heart and probably result in interference with the circulation in the coronaries. The latter factor is a most important one, for it leads to cardiac inefficiency and eventually to fatty or other degenerative changes. In aortic regurgitation, the process is not limited to the short period of the ventricular systole, but begins as soon as the systole terminates and continues throughout the ventricular diastole, during the whole of which period the backflow from the aorta into the ventricle is aided by the aspirating effect of the dilating ventricle. It is obvious also that there will be interference with the circulation in the coronaries and that degenerative changes in the cardiac muscle will almost certainly result. In short, Wilson states that the new teaching is that systolic murmurs existing alone and without other disqualifying signs and symptoms should be ignored, a truth whose general recognition will free a considerable section of the community from a needlessly restricted life. Diastolic murmurs, on the other hand, have always had a serious significance.

The Treament of Amputation Stumps.—A. Horwitz has charge of a service where all amputated cases are sent for the object of having a prothesis adopted. He divides his cases into two groups: (*A*) unhealed stumps, (*B*) healed stumps, but still not in a condition for an artificial limb. The first group (*A*) offers three kinds of conditions which should be treated each apart, namely: (1) *Granulation of the wound.* Treatment with ointments (zinc, silver nitrate, etc.) or by hyperemia (heliotherapy, hot air). The employment of skin extension, thus giving the integuments a chance to become invaginated on the granulating surface. The operation finds its indications only if the granulating surface is absolutely clean and consists in mobilizing the skin. (2) *Fistulous stumps* should be operated. Remove the ligatures or sutures which keep up the suppuration or look for a sequestrum. (3) Stumps with protrusion of the bone ends due to an inefficient excision at the time of the primary operation or to retraction of the integuments, should be treated by extension on the integuments which may result in covering in of the raw surfaces, but usually this attempt is quite insufficient. Secondary amputation must be done or a plastic operation, with a cutaneo-adipous flap taken from the trunk or other area, but never from the limb involved. (*B*) Soft cicatrics directly covering the bone ends are to be excised, the skin then to be brought over the bone and the latter to be resected again later on if necessary. Painful stumps are to be dealt with by mobilization of the integuments in order to free neuromata and thus put an end to their irritation. Contractures are relieved by massage (*sic*) and passive motion. At the knee tenotomy of the flexors and later supracondylar osteotomy of the femur should straighten the limb to complete extension. Edematous stumps, muscular retraction, etc., are not in condition for a prothesis and therefore should be massaged, bandaged tightly and hardened by alcohol dressings.

A Modification of the Conradi-Kayser Technique for the Culture in Bile: A Contribution to the Question of Growth of Typhoid Bacilli Taken from the Blood.—Seeliger has endeavored to detect the faults of the present technique of culture of typhoid blood in fresh ox-bile combined with peptonized glycerin. The changes that he has made have allowed the writer to obtain positive results in a greater number of instances, and, particularly, for a longer time during the duration of the disease. The following is, briefly, Seeliger's technique. Several c.c. of the patient's

blood are mixed in 5 c.c. of bile. Shake. At the laboratory, quite a large amount of bile is added to this mixture, and then it is placed in an oven for forty-eight hours. After this lapse of time ten cultures are taken from the surface of the liquid, and ten others from its midst, and then inoculated onto proper culture media. The plates are then placed in the oven until the day following. At the time the twenty cultures are taken, add 3 c.c. broth to the tube of bile, shake and place in oven for twenty-four hours. Should the first cultures remain sterile, inoculate a plate with the bile to which the broth has been added. Reinoculations to the extent of three or four are to be made if plates Nos 1 and 2 remain negative. The table given by the writer shows that plate No. 2 gives positive cultures when plate No. 1 remains sterile. At other times a positive result is only obtained on plate No. 4. This sensitizing technique has permitted one to detect the typhoid bacillus in blood taken from patients in the fourteenth week from the beginning of the disease, a fact which disproves the idea that the organism can only be found in the blood during the first few weeks.

Death Following Blood Transfusion.—H. Kuczynoki reports an interesting case of the death of a man one hour after transfusion of 120 c.c. of blood. At autopsy an occlusion of the small pulmonary vessels due to the detritus of hemolysis, was discovered. The writer, although not denying the utility of blood transfusion, insists upon the necessity of blood examination of both the donor and receptor from the standpoint of their respective hemolytic reactions and that this examination should precede every transfusion.

Generalized Xanthomatosis and Diabetes.—O. Lubarsch offers the following considerations on the genesis of localized or generalized xanthoma, and on its relationship to metabolism and the circulation, based on a personal case history. He concludes that there is a sanguineous inundation of products of disintegration of the lipoids as well as their accumulation in the lymphatic tracts. Local deposits or general infiltration are determined by circulatory stasis and should the stasis subside, the xanthomata may disappear by passage of their lipoids into the general circulation.

Treatment of Typhoid Carriers with Mercurial Cystin.—W. Geiger, having taken up Stuber's experiments (*Münchener medizinische Wochenschrift*, Feb. 19, 1918; MEDICAL RECORD, May 18, 1918) concludes that this treatment is worthless. Stuber's results can be explained by the selection of subjects in a more favorable condition for a rapid cure and also from the fact that this experimenter dealt preferably with paratyphoidal germ carriers. Geiger, on the contrary, was unable to obtain any result in carriers of true typhoid, when this condition had existed for several years. (Even the Huns disagree among themselves.)

A Case of "Transvestitism," with Highly Ovariolytic Blood Serum.—H. Lelewer has observed a male subject offering unquestionably the somatic characters of his sex. In spite of this fact his mental feminism was revealed by certain peculiarities in his sexual life, although there was no true homosexuality. Besides, this man had a decided desire to wear female attire (transvestitism). The patient's blood serum, examined by Abderhalden, showed a large percentage of substances destroying ovarian tissue. Lelewer looks upon this case as a proof of modern ideas concerning hermaphroditism. This phenomenon is due to the persistence, in the sexual gland, of endocrine elements of the opposite sex to that of the bearer of these elements. This peculiarity is quite compatible with an external secretion absolutely unisexual in nature, as is made evident by the case history recorded by the writer.

May 18, 1918.

Operative Shortening of the Styloid Apophysis in Disturbances of Deglutition.—L. Rethi has had occasion to attribute pharyngeal pain in two patients to an excessive length of the styloid apophysis. These cases were characterized by the uselessness of medical treatment (cocaine, iodine, argenti nitrate) and by a hardness at the level of the tonsil. The incision of this organ, followed by excision of 1 centimeter of the styloid apophysis, resulted in a complete disappearance of the pain. Rethi next passes in review the rare cases in which this operation has been resorted to; sometimes only causing fracture of the apopyhsis without excision. This, being accomplished with the finger, may give the same results as the open operation performed by the writer.

The Objective Test for Ascertaining the Reality of Deafness or Diminution of Hearing.—M. Falta employs Bárány's apparatus for the introduction of a rapid and momentaneous sound which can be set up by merely pressing on an electric button. The subject under examination reacts against this unexpected noise by movements of the eyelids and a tremor involving the entire body, when the case is one of simulation. The writer affirms that a deaf person or one that does not hear the spoken voice at a distance of 10 centimeters will never offer any of these reflex manifestations.

Project of a New Program of Medical Study.—R. Stigler states (as medical teachers outside of France and Germany know only too well) that anatomy is, generally speaking, taught in too great detail, much to the detriment of both general and synthetic instruction of the human body. Histology should be taught in its relations to the functions of the organs studied. On the other hand, physiology, which is the fundamental branch of medical study, is too much neglected. A special term should be given up to it, as is done at Harvard (at the University of Geneva it is three terms), as it is in this branch that the personal work of the students should be encouraged by lectures, discussions, etc. Besides, Stigler would wish to see a clinical service connected with all institutes of physiology, in order to present to the students the functional disturbances in man in conjunction with provoked experimental disturbances in the animal.

Journal d'Urologie.

Management of Inflammatory or Traumatic Strictures of the Urethra in Soldiers.—Pasteau makes two types of cases. First, the complication is more important than the stricture. Unless these subjects can be made to care for themselves they should be invalided to the rear. Second, the stricture is the important thing. If it is of gonorrheal origin dilatation will usually render the subject equal to military service. This resource, as well as internal urethrotomy, will have to be rendered at a special genitourinary station in the army or in the interior. If the stricture is traumatic dilatation will be of no avail save in the mild case and the subject should be treated by urethroplasty at some one of the civil centers for genitourinary work. No patient with uncomplicated stricture should be discharged outright from the army. The complications, as a rule, will not prevent the soldier from all forms of military activity, for if incapacitated from full military duty he can be utilized in the auxiliary service. Only in very severe complications such as fracture of the pelvis, complicating a wound of the urethra, will it be necessary to retire the victim outright.

Management of Traumatisms of the Kidney in the Dressing Sections at the Front.—Noguès lays down the following rules: Immediate intervention is called for in trauma of the kidney and ureter only in presence of a serious hematoma, a profuse or prolonged hematuria or a projectile lodged within the kidney. Escape of urine from the wound does not straightway necessitate a nephrectomy. The latter operation, in the interest of the best economy, should not be performed save in case of absolute necessity. In case of doubt as to the existence of a uretorenal lesion the hospital card should mention all of the phenomena which might eventually aid in making the diagnosis.

Urethral Calculus.—Maringer relates the case of a urethral stone which formed behind a congenital stricture seated at the juncture of the spongy and membranous portions. The patient was sixty-five years

old, of feminine or infantile appearance. There was marked hypoplasia of the genitals, including absence of a prostate. Patient seems to have been unaware that anything was wrong until retention suddenly set in. There was no cystic reaction. The stone was originally of calcium oxalate with a urophosphatic secondary deposit. The stricture was dilated until the stone could be expelled by the patient.

Le Progrès Médical.

March 30, 1918.

Acquired Morbid Fear.—Voivenel states that the present war is a grand laboratory for the study of the emotions and emotionalism—of the intellectual and emotional alterations of the wounded. It has been shown that a symbiosis of neuropathic and circulatory phenomena is very common, some of the latter being actually due to implication of endocrine glands (thyroid, adrenal). In commotional conditions there is an emotional factor and the so-called mental confusion of warfare may perhaps prove to be a special psychosis. A subject of the greatest importance in this connection is predisposition. That a notable one exists is of course recognized by all and the sole question for agitation is the possible absence of predisposition. Under the latter term something more than heredity may be comprehended, for acquired states may serve as predisponents. Hence we may find in one subject two kinds of predisposition, to wit, neuropathic inheritance and some acquired state, such as syphilis or alcoholism, or a severe wound or commotion. In not a few cases several powerful predisposing factors exist side by side. A distinction is also possible between immediate and remote factors. In passing to the subject of morbid fears the author makes four causes, of which one is essentially predisposition, the others being commotion, somatic defects, and emotion in the stricter sense of the term. Bases of each are given. The first occurred in a debile of undoubted courage, who failed to appear when his battalion was ordered to form ranks. The testimony of his corporal made it evident that the soldier was in a state of stupor due to fatigue and emotional stress incidental to the campaign. His past record as a soldier was excellent. He was acquitted of breach of discipline and later retired as unsuitable for fighting. A second soldier suffered from post traumatic mental confusion and, despite a fear of being wounded, had remained at his post until during a bombardment a shell fell near him, upon which he fled from irresistible impulse. He also was acquitted. Under the head of somatic defect would come cases of Graves' disease and hereditary cholemia, which are cited by the author. Both subjects were officers who had been of conspicuous bravery. One had recently been through influenza, while the other had been gassed. Both, who had been seized with a panicky fear, were acquitted and ordered to rest up and recuperate. Under the head of pure emotional cause several cases of irresistible fear are given. An artillery man who had shown fear at seeing his comrades killed in battle and who did not improve in this respect, was ordered by his colonel to sleep in the artillery park—not as a punishment, but for his own good. Two months later he became an aviator and died on the field of honor. Another soldier with only a slight element of predisposition developed as a culmination of a series of small emotions an anxiety neurosis as a result of which he had to be retired from the ranks for a long period.

Ablation of Rectal Cancer by the Coccygeo-Perineal Route.—Demarest by combining these two routes of attack in the interest of saving the sphincter, has during the past 3 years operated on 21 patients out of 40 who presented themselves with cancer of the rectal ampulla. The technique is not original, for the author states that it was published by Cuneo in 1908. He makes his first report of his experience with the intervention. Rectal cancer is relatively slow of evolution and often no lymphnode metastases develop. If then we establish an iliac anus we often confer upon the patient 3 years of not too burdensome survival. But this fact, so far from contraindicating surgery, is actually an incentive to try to cure the case, or would be were it not for rather high operative mortality and frequent bad functional results. Everything must depend on the diagnosis of operability, and here belong the cases of the inferior portion of the ampulla and anal canal. Cancers above or level with the tip of the exploring finger are always serious from the operative viewpoint. The author's personal experience shows that relatively benign cases occur as high up as the middle of the ampulla. Of the author's 21 cases, 15 were of this quasi-benign type. In this series there was one postoperative death from pulmonary congestion. In cancer above this level the results are far from encouraging, although better in women than in men. He would no longer operate for these high growths in the latter. In four such cases he failed to accomplish any good and two patients died of the operation. Of the others, one succumbed of secondary operative mortality, while in the other it was necessary to make an iliac anus. Of four similar cases in women but one ended unfavorably, while another was left with a fistula. In addition to five deaths he has had two recurrences, one of which supervened very soon after intervention. There are therefore 15 patients living and free from recurrence (slight discrepancies in the author's figures are probably due to citation of certain cases before the 3-year period). In regard to functional results, 11 subjects are free from anal deformity and the integrity of the sphincter is demonstrated by its contraction upon the exploring finger. However, there is incontinence for gas, and fluid feces are not completely retained. These patients when somewhat constipated have excellent control. However, the tendency in these cases is toward increased tonus of the sphincter which is sometimes regained at an early period.

March, 1918.

Mercury Idiosyncrasy.—Gjessing refers to the relative infrequency of idiosyncrasy to mercury. Several important reference works ignore the subject. The following case is narrated. A woman aged 35 consulted the writer for a left-sided affection of the lacrymal passages. A probe was passed into the inferior canaliculus and some adrenalin sublimate solution instilled, most of it escaping by the nose. In the evening patient presented marked edema of both eyelids and face, extending to the throat. There were no evidences of an inflammatory reaction. Atropine was given internally and boric acid solution locally applied. On the following forenoon the edema had reached the clavicle below and had crossed to the opposite eyelids. Although both eyes were swollen shut there was no chemosis. The patient continued the use of $\frac{1}{4}$ mgm. of atropine t.i.d. and at the expiration of eight days the swelling had all subsided. In investigating the case in detail it was found that the patient was about 6 weeks pregnant. She had never shown any food idiosyncrasies. When cocaine had been used as a dental anesthetic no trouble had resulted. The only unusual discovery was a tendency to form suggillations at the site of minimal traumatisms, but there was no suggestion of true hemophilia. She had gone through three pregnancies without morbidity, but during the last had presented headache and albuminuria without influence on the course of gestation. We know that most subjects can tolerate mercury locally, although some react with erythema, etc. In mercurial idiosyncrasy a minute dose is sufficient to provoke it. In several recorded cases minute quantities of white precipitate and other mercurial ointments when applied for blepharitis have caused extreme swelling of the lids with chemosis of the bulb. Yet we know that calomel, sublimate solutions, and various ointments are used in routine in eye clinics throughout the world and that idiosyncrasy to such drugs may never have been encountered by some clinicians. Under mercurial idiosyncrasy we must not include cases of chemical reaction in the eye when calomel is applied locally to subjects who are taking iodides internally.

Book Reviews.

Les Plaies de Guerre et Leurs Complications Immédiates. Leçons Faites à l'Hotel-Dieu. Par Henri Hartmann, Professor de Clinique Chirurgicale. Prix, 8 Francs. Paris: Masson & Cie., 1918.

These lectures, which were delivered during the winter of 1916-1917, were intended as a résumé of what has been learned during the present war in respect to the treatment of wounds. The number of lectures is eighteen and the complications discussed include hemorrhage, tetanus, gas gangrene and traumatic shock. The forms of wound discussed involve respectively the soft parts, bones, and joints, while special attention is directed to wounds of the cranium, face, orbits, thorax, abdomen, and the larger articulations. There are lectures on apparatus, amputations, and frozen feet. The volume is illustrated with fifty-eight text figures. The 200 pages are solid descriptive text and there is no padding with case histories. The effort may be said to represent the activities of the Paris Surgical Society in the treatment of war wounds.

Ambulance de "L'Océan" La Panne Travaux Publiés sous la Direction de Dr. A. Depage. Dr. A. P. Dustin et Dr. G. Debaisieux. Tome I. Fasc. II. Prix, 14 Francs. Paris: Masson & Cie., 1917.

The first fasciculus of this work was noted in the review columns of the Record. The present volume of 381 pages and freely illustrated comprises a number of important studies, in which are considered treatment of wounds, bone grafts, post-traumatic lesions of nerves, influence of traumatisms on the choroid plexus, latent sclerosis, histopathology of muscle, flora of war wounds, physiopathologic properties of exudates, antiproteolytic properties of serum, content of blood serum in alkaline reserves, posthemorrhagic anemias, etc. This publication is intended as a serial with two fasciculi annually, but without any fixed dates of issue. Few military hospitals are exhibiting such a utilization of their opportunities and one wonders "how they do it." The mechanical work is also excellent.

Blessures de la Moelle et de la Queue de Cheval. Par G. Roussy et J. Lhermitte. Collection Horizon. Prix, 4 Francs. Paris: Masson & Cie., 1918.

This volume was written to fill a gap in war neurology. That such a gap exists is due to a number of causes. Opportunities for intensive study and for following up cases to end results have been few and the average military surgeon does not see a very large total of these injuries. The latter are divided into complete and incomplete division of the cord, commotion of the cord and lesions of the cauda equina. There is a full chapter on complications—meningomyelitis, eschars, urinary infection, thoracic and abdominal complications, edema and arthropathics. Among the typical operations described are laminectomy, meningo-myelorrhaphy and meningorrhaphy. The volume is illustrated with eight plates.

Handbook of Operative Surgery. By William Ireland de C. Wheeler (Mod)., B.A., M.D. (Dub. Univ.), F.R.C.S.I., Lieut.-Col. R.A.M.C. Surgeon to Mercer's Hospital; Member of Council, Royal College of Surgeons, Ireland; Surgeon to the Military Orthopedic Center, Blackrock, and Hon. Surgeon to the Forces in Ireland. With an Introduction by Surgeon-General Sir Alfred Keogh, G.C.B. Third Edition. Octavo of 364 Pages, with 226 Illustrations. Price, $3.50. New York: William Wood and Company. 1918.

This work is intended for junior practitioners of surgery and is essentially an elementary work. In view of the fact that just now British graduates from medical schools immediately enter war service, the author planned to give the greatest space to subjects of the greatest immediate importance under such conditions. Thus we find at least one-third of the book devoted to ligations and amputations. Operations of urgence, such as tracheotomy, are clearly and concisely described, and there are short descriptions of most of the major as well as minor operative procedures. In a book of such elementary character it seems strange that so much space is given to tendon and nerve surgery, for certainly the fledgling surgeon will not be entrusted with operating in such cases, while the more experienced surgeon will require more exhaustive discussion of the subject for it to be of much value to him. The chapter on transfusion is much out of date as far as this country is concerned, for there is no mention of the methods of Lindeman, of Lewisohn and Weil, or of Unger. Charts showing the channels of collateral circulation after ligation of principal arteries are very instructive. The illustrations are usually good, but not always co-ordinated with the text. Considering the size of the book and the intentional brevity of descriptions, the author has produced a work which well answers the purpose for which it was intended.

Shall Disease Triumph in Our Army? A Plea for the Reorganization of the Medical Department of the United States Army. By Major Louis Livingston Seaman, Late Surgeon-Major, U. S. V. E., New York. Published by American Defense Society, Inc. No date.

The date of the preface of this work is 1906 and it is said to consist of extracts from a volume entitled "From Tokio Through Manchuria with the Japanese," which appears to have been published by the Appletons in 1904, and from the author's "The Real Triumph of Japan," published by the same house in 1906. The American Defense Society contributes no preface or introduction and the object of reissuing the book is unknown. One who reads the paper cover gets the impression that the book is a reflection on the present medical department of our army. The work is, of course, a glorification of the medical corps of the Japanese army. Since that period military medicine has been revolutionized in certain directions, notably the immunization of soldiers, and our medical corps is certainly not behind that of any other country in progress and efficiency.

The Spleen and Anemia. Experimental and Clinical Studies. By Richard Mills Pearce, M.D., Sc.D., Professor of Research Medicine. With the assistance of Edward Bell Krumbhaar, M.D., Ph.D., Assistant Professor of Research Medicine, and Charles Harrison Frazier, M.D., Sc.D., Professor of Clinical Surgery, University of Pennsylvania. 16 illustrations, color and black and white. Price, $5.00. Philadelphia and London: J. B. Lippincott Company.

The relation of the spleen to anemia has long been a source of much scientific interest and speculation. In the present volume the authors have endeavored to clarify our knowledge of the subject and have added extensively thereto from their own researches. The problem is approached from the experimental point of view. The experiments were carried out on dogs over a period of five years and reveal a large amount of painstaking work. The book is divided into three parts. The first part, which is written by Dr. Pearce, deals with the effect of splenectomy in dogs; with the supposed regulatory influence of the spleen in blood destruction and regeneration; with changes in the bone-marrow after splenectomy; with changes in the liver and lymph nodes; with metabolism studies before and after splenectomy in dogs and man. The data derived from these researches form the basis of the clinical observations contained in the second part, written by Dr. Krumbhaar. This part is concerned with the classification and analysis of types of splenomegaly accompanied by anemia, such as splenic anemia, Gaucher's Disease, Banti's Disease, Von Jaksch's Disease, acquired and congenital hemolytic jaundice, and pernicious anemia. Methods of diagnosis, prognosis, and treatment (other than splenectomy) are discussed from all angles. Particularly valuable are the diagnostic procedures detailed in connection with the various types of splenic disease. A final chapter, comprising the third part, is devoted to the surgical technique of splenectomy and the preparation and after-care of the patient. This part is written by Dr. Frazier and leaves nothing to be desired.

A list of 486 references to the literature is appended. The book contains several excellent plates illustrating the histopathology of the clinical types of splenomegaly associated with anemia, as well as the different steps in performing splenectomy. The work forms a distinctive and noteworthy addition to our knowledge of an obscure problem.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-third Annual Meeting, Held at Atlantic City, N. J., May 7 and 8, 1918.

DR. F. H. WILLIAMS OF BOSTON, PRESIDENT.

(*Concluded from Vol. 93, page 1068.*)

The Course of Myelocytic Leucemia as Influenced by Splenectomy Following Radium Treatment.—Dr. H. Z. GIFFIN of Rochester, Minn., gave this paper. He said the history of splenectomy for myelocytic leucemia was a very tragic story. Few cases with recovery had been reported. There was a 93 per cent. mortality. If reduction of the spleen before operation by means of radium could be effected, the mortality could be considerably lowered. Twenty cases were now reported in which radium treatment had been given preliminarily. Of these nine patients had died after varying lengths of time, one year or more. Of the living patients the disease had apparently progressed as it would without splenectomy. It did not seem to have been altered in any way. The only advantage was an addition to the comfort of the patient. Whether this was a justification of the operation Dr. Giffin was not prepared to say.

Dr. G. DOCK of St. Louis said that he had a case, the patient being a man of sixty-one, who had never had occasion to consult a doctor for any illness and had been doing active work for forty years. He had an administrative capacity at a university. He was a big eater, but took little exercise. He was apparently vigorous, but medical men would look upon him as arteriosclerotic. He denied syphilis and had no scar, but the Wasserman was 4+ and it was found that he had a marked arteriosclerosis. After a Christmas dinner he was returning to his house and climbing a small hill, when he felt a severe pain radiating down the left arm and was obliged to stop. The physician who attended him said it was angina pectoris and high blood pressure, and gave him nitroglycerin. The man went to work until January 6, when he had another attack and was brought to the hospital. He had air hunger to a marked degree and the larynx worked with extreme violence. Morphine and atropine relieved his symptoms. He never got over the orthopnea. Later he developed hydrothorax. Dr. Robinson took the electrocardiogram and, without knowing that a diagnosis of coronary thrombosis had been made, he stated that the absence of the T-wave would suggest coronary obstruction. The patient died of double hydrothorax twenty-three days after the first angina pectoris attack. Post-mortem examination showed very marked syphilitic arteriosclerosis. There was thrombosis of the descending coronary with an infarct three weeks old.

Dr. E. LIBMAN of New York said that the subject of coronary thrombosis was one of the most important in clinical medicine. Many cases no doubt occurred, but autopsies were few. The question of how long a patient might survive was an important point. The patient could be recognized by the color of his face, which was peculiar and which indicated that at some time or another the patient had suffered from coronary thrombosis. Sansom had given a description of the color, but had misinterpreted the cause, which he thought was aortitis. Such patients, he said, had a peculiar leaden tint or earthy hue of the skin, which always indicated closure of the coronary. Aortitis usually had an ashen pallor. Such patients did not stand operation well, but became pulseless and went into a condition which was misinterpreted as shock. The question as to what part of the coronary was involved was important. One could sometimes say that the right branch was closed, but there was usually a left coronary thrombosis. In several cases Dr. Libman said he had been able to diagnose right coronary thrombosis. This was apt to be accompanied by a very marked enlargement of the liver. This was important for diagnosis and different from the pain of the liver that was sometimes noted. Further progress in diagnosis would have to be based upon electrocardiographic studies. In course of time one would be able to say which part of the heart muscle was involved.

Dr. S. J. MELTZER of New York said that he would like to say a word on the experimental side. It should be kept in mind that human cases were not identical with ligation cases. Ligation affected other tissues. It might be nervous structure (in spite of the myogenic theory) or it might be the conductive system. One could not be sure that the ligation was thorough enough or permanent enough. Ligation was not the same thing as thrombosis. It would be well to repeat the old experiments from a new viewpoint—to occlude the coronary artery without ligation. He would like to know what method was used for artificial respiration. With intertracheal insufflation a good surgeon could close up the lesion peripherally so the dog would be in a normal state.

Thrombosis of the Coronary Artery.—Dr. J. B. HERRICK of Chicago presented this paper. It was stated that death need not immediately follow obstruction of the coronary artery. Cases were commoner than was supposed. An accurate diagnosis could be more frequently made. Cases might be arbitrarily divided into four groups: (1) Those with instantaneous death; (2) those in which death soon followed; (3) those in which death occurred weeks or months later; (4) a hypothetical group, in which symptoms were very slight, being merely an obstruction of the twigs of the artery. The third group was important. In such cases patients had frequently had angina pectoris and they described the occurrence of the coronary obstruction as the most acute and prolonged attack they had ever had. The pain usually was referred to the epigastrium. Occasionally it simulated an acute abdominal syndrome and careful differentiation was necessary, as unnecessary operations were sometimes performed. In regard to experimental work on this subject. The ligation of the coronary artery in dogs had been done and the electrocardiogram studied. Dogs could live weeks and months after the ligation or might finally recover. In certain ligations the lesions were produced in the myocardium. They were most marked in the endocardial or subendocardial locality, or conductive region of the heart. Such phenomena as auricular or ventricular fibrillation were produced with changes in the electrocardiogram in the T-wave. This work might interpret abnormalities in the human electrocardiogram and later work might serve to show just which branch of the coronary was obstructed. The work, it was hoped, would be confirmed by autopsy findings and study.

Dr. H. A. CHRISTIAN of Boston said he would like to refer to two groups of cases mentioned by Dr. Christian. The first, those with symptoms below the diaphragm, which simulated abdominal conditions. These were frequently operated upon. A diagnostic point was the remarkable fall in systolic blood pressure. The diastolic pressure was little altered. The pulse pressure was strikingly small. Another group of cases was that in which thrombosis took place with very few symptoms; the patient, while sick, did not present a characteristic picture and the sudden death of the patient caused surprise. This was caused by rupture through the softened heart wall and death from hemorrhage. From a pathological study of these cases it was evident that a chronic thrombosis had taken place, but when it had occurred it produced very few symptoms.

Dr. HERRICK, in conclusion, said that it was not possible to duplicate exactly the diseased condition as it occurred in man. The method of ligation of the coronary with silk was used. The dog was etherized and tracheal insufflation was done. This opened a great field for experimental work in the way of producing chronic obstructions. In the human subject the occlusion of the coronary was not always complete. In animals many remained healthy for some months. They were then killed. Dr. Smith lost one animal in the ligation process. He had expected that someone would raise the question as to whether these electrocardiograms were produced by digitalis. They were not so produced.

The Serum Treatment of Meningitis.—Dr. SIMON FLEXNER of New York read this paper. He said that his remarks would be of an introductory character, the speakers who would follow would dwell on the more specific points of the subject. He would recall the historical sequence of events which would explain the progress now being made. The serum treatment of epidemic

meningitis began in 1907. It corresponded with the decline of the severe wave of epidemic meningitis which spread over Europe and America in 1904-5. At the time there was a general confirmation of the work of Weichselbaum, who found that the meningococcus was the cause of meningitis throughout the world. For the first time then figures were obtained as to the mortality of the disease, diagnosed bacteriologically, and also of the prevalence of any other cases of meningitis. A notion of the mortality according to localities and the fluctuations in mortality and incidence according to districts was also obtained. That epidemic gave a satisfactory etiological basis to work upon and a definite basis of mortality on which could be erected a conception of the value of therapeutic measures. At that time arose the conception of the serum treatment of meningitis. There had been earlier experiments, but with the increase in knowledge of immunology relating to many other bacteria, corresponding tests were made relating to meningococci. No serious effort had been made, however, to use antisera before 1906. Before discussing how the serum came to be supplied, one must ask what the idea was of the pathogenesis of the disease at that time. It was known that the meningococcus of Weichselbaum caused the disease; that this organism localized very quickly in the tissues of the central nervous system. It was found present upon the nasopharyngeal mucous membrane, both in persons having the disease and in healthy persons. The latter were called "carriers" of meningococci. The localization of the meningococcus on the nasal membrane, where it did no harm, and its presence in the meninges, where it did great damage, raised the question as to how it got from one place to the other. There was no agreement as to its mode of penetration. If blood cultures were made in persons in the first days of the disease, positive cultures were often obtained. The significant point was obvious—it first got into the blood, from thence into the meninges, or perhaps secondary infection of the blood took place. Both of these suppositions would account for the pathological process. The meningococcus might penetrate the blood stream, because at certain periods of the disease metastatic infections occurred. With involvement of the meninges were seen involvement of joints, thorax, eye, etc. It was clear that the organism could penetrate the blood, but there was no decision as to whether meningococci on the nasopharynx could penetrate directly through the lymphatic connections of the nasal mucous membrane into the blood, thence into the meninges. On the whole, the opinion was that blood infection was secondary and that the meningeal infection was lymphatic, by direct extension. Quite another conception was now held of the mode of infection, on the basis of which better practice had been established. Practice, based on the older opinion, was influenced by the circumstances under which cases came under clinical observation. These cases appeared in the civil population. They were observed for hours, days, or weeks before diagnosis of meningitis was made, perhaps before it could be made, and when these cases were observed there was a well established infection of the central nervous system. Under these circumstances it was obvious that antisera, to be effective, must be injected directly into the subarachnoid spaces. Studies since that time indicated that this was the correct procedure and that to use other means was to lean on an insecure reed. The bacteriemia, however, should also be given attention. If the antiserum was effective in the meninges, it would probably also be so in the blood. It was argued that serum introduced into the meninges found its way into the venous blood and became absorbed. It was thought that the blood infection, occurring late in the disease, could be reached and controlled through the subarachnoid space. Upon this question military organization had thrown a new light. With men entirely under medical control very much improved technique could be instituted. Many cases, it was found, could be aborted by early intravenous injection of the serum so that the character of the case was changed. This situation was now entirely appreciated in this country and a glimmering of it was dawning abroad. Another important point now being realized was that (according to Dopter's work in 1909) the meningococcus was not a fixed form, but involved a group, just as dysentery organism formed a group. Two strains might be distinguished culturally, but not clinically. Each strain had a number of variants. Specific therapy, to be effective, must be truly specific. It must be applied to variations in types of the microorganism. Dosage must be in accordance with immunological relationship. Antibodies must be adapted to antigenic properties of the organism. At present a movement was on foot to substitute a monovalent serum for a polyvalent meningococcus serum, just as soon as the exact type of organism could be obtained. Whether this would be a great advantage only the future could tell. Dr. Flexner said he hesitated to express an opinion, as the work necessitated a large staff of trained bacteriologists to examine the strains. It would take a long time to train enough men to make the procedure sufficiently accurate and safe. These reasons, however, would not be lasting, and it was impossible to produce a polyvalent serum of as high a type of specificity to a type, as the monovalent serum. This aspect of the subject was now under careful investigation.

Intravenous Serum Treatment of Cerebrospinal Meningitis.—Dr. W. W. HERRICK of New York made this presentation. He said that in the military cantonment life there had been an unusual opportunity for clinical research, and this had been used as a means of making and keeping men fit for active service. Epidemic cerebrospinal meningitis had received special study. Cases had been seen early and it was thus possible to control them effectively. It was stated that the disease was not primarily a meningitis, but took the form of sepsis in the blood stream, which later localized in the meninges. Forty-five per cent. of the cases were discovered in the pre-meningeal stage, with generalized infection and no local involvement. About two weeks after the blood stream infection the meningitis was present. One case was seen, the patient being the head nurse in the ward, who had polyarthritis, due to meningococci; she was treated with antiserum intravenously and made complete recovery. Complications of the disease were many—pleuritis, orchitis, pericarditis, arthritis, etc., were noted. Early cases responded at once to intravenous treatment. The method of treatment was similar to Cole's method with lobar pneumonia. The patient was given a desensitizing dose at the earliest possible moment, then after a dose of morphine and atropine was given a test dose of serum intravenously. The serum was introduced slowly, at a rate of not more than 1 c.c. per minute. If untoward signs appeared the treatment was suspended, but renewed a little later. As much as a 150 c.c. dose had been given in serious cases. Treatment with large doses had proved of value and it was found that cases receiving 500 c.c. did better, and that there were fewer deaths. If the intravenous treatment was to have any success at all, it had to be used boldly and in large amounts. The intraspinous method had not been neglected, but it was not used in the pre-meningitic stage. The combined treatment had been successfully applied. In serious cases, with the patient unconscious and covered with a rash, recovery to the point of being out of danger had been seen within forty-eight hours. The largest intravenous dose that had been given was 705 c.c. and the greatest number of injections ten. Disappearance of the meningococci was seen within a few days. These cases had shown very little delirium, which was characteristic of the 1904 epidemic. It was felt that if the cases could be diagnosed early and treated by the intravenous method, and the later cases treated by the combined method, that the mortality could be kept down to 15 per cent. These epidemics would in future be considered with more equanimity than they were in the past.

The Essential Properties of a Potent Antimeningococcic Serum.—Captain H. L. AMOSS, M.R.C., read this paper. There were three essential points to bring out: (1) passage of immune bodies from the blood to the spinal fluid; (2) mechanism of infection; (3) essential properties of the antimeningococcus serum. The passage of immune bodies in poliomyelitis was studied and was considered possible only under the conditions of increased permeability of the choroid plexus. It was supposed this would hold true with the meningococci. This was measured by agglutinin reaction in the cerebrospinal fluid. With a greater degree of inflammation

the agglutinin would go through in greater concentration. After an intraspinous injection there was disappearance of agglutinin from the blood in 7 hours. There was noticeable a blocking effect on the immune bodies in the cerebrospinal fluid after intravenous injection. This had not been definitely measured as yet. It was found that unless the permeability of the meningochoroid plexus was increased there was no passage of antibody. A certain accumulation of immune bodies was first necessary in the blood stream to produce this effect. As to the mode of infection—a virulent culture of meningococci introduced intraspinously would cause meningococcaemia in a few hours. It remained to be seen whether the organism in the blood stream would produce meningitis. This did not follow, although the organism remained viable 48 hours. Meningitis was not produced in the monkey by this means, although it should be remembered that the monkey was a comparatively insusceptible animal. In regard to the antisera: Reactions were always complicated by differences in the strains. The sera produced by the parameningococcus being very different from those produced by the regular meningococcus. To get a potent serum the antibody zone should be raised. Less specific antibodies as well as the agglutinins were necessary factors. In sera which gave markedly different results in treatment, there was no difference to be detected except that of agglutination. In the making of a monovalent serum the difficulty of getting cultures was a great drawback, not more than 50 per cent. of cultures being obtained. It was doubted whether a high enough titer could be obtained with the monovalent serum to warrant the efforts spent in its production.

Dr. William H. Park of New York said that the laboratories producing serum were in great difficulties as to how to get the best serum. Dr. Amoss had said that the agglutinating properties were the chief differences in the antisera and that the agglutinating power was a measure of the curative power. This was not the case with the pneumococci. Why should the agglutinating power be a measure of the curative power when the sera were equal in infectious power? The anti-infectious power was the curative power. The agglutinative power did no doubt show whether the serum matched the strain, which the complement fixation test did not show in this case. In the treatment of cases at the Board of Health laboratory in New York they had not been able to prove that the serum produced a large number of strains differing in its curative power. That, it was thought, was borne out by the pneumococcus serum. The best were those weak in agglutination. Dr. Flexner had said that he doubted whether the cases among the civil population would show the benefit of intravenous treatment. In the last few years the Board of Health had noted a mortality of 22 per cent. in New York City. The giving of a subcutaneous injection to a child had been mentioned, that was done in the earliest cases in New York City. It would not be wise, however, unless the intravenous method was found impossible.

Dr. Henry Koplik of New York said that these differences in the civil and military aspects of the disease were interesting. Granting that, as Dr. Herrick had said, the cases were at first a generalized sepsis, in some instances this was so mild as to be inappreciable. In a great majority of cases of children, in civil life, the localized manifestations would call for more intensive treatment than that for general sepsis. Several cases had recently been seen where the constitutional element was more predominant than the meningitic element. A child, in apparently good health, was taken with a convulsion, became covered with petechial rash, became unconscious and then died. No meningococci could be shown in the smear or in the cerebrospinal fluid. Such cases could be reached by intravenous injection. In spite of the low mortality, these methods could save a few more lives each year than was being done at present.

Dr. S. J. Meltzer of New York said that Dr. Flexner had not mentioned one point and he had expected to hear it stated by Major Herrick, that was how the epidemic terminated and the reason for it. This was an omission of a very important point. In regard to the passage of the infection through the choroid plexus: as soon as the entry of infection was supposed to be the nose and throat, it was very natural to consider the idea of an ascending infection which would finally pass through the choroid plexus. It had been said that it passed by way of the lymphatics; of course, if it did that, it entered the blood stream. It should be said that the infection passed through the lymph spaces. Dr. Meltzer said he never could understand why it should be the choroid plexus alone that was affected; if the blood stream was reached and the arteries, the cord and parts below the cord would be involved. Since there was no definite evidence that the central nervous system could not be reached by the blood at the same time that other organs were affected, he would like to ask for an expression of opinion why there was no involvement other than the choroid. He would rather say that the capillaries and other parts of the central nervous system also suffered change in permeability.

Dr. L. F. Barker of Baltimore said that complications like polyarthritis, pericarditis, etc., came late in the disease. If bacteriemia were present one might expect complications of that kind. In the gonococcal bacteriemia after urethritis there often occurred a polyarthritis which later became suppurating. Infection might occur early and only become apparent late in the disease. As to giving intravenous treatment only when general sepsis was present, he would think that it could be used to combat local infections and to discourage any foci that had become established as the result of the bacteriemia.

Dr. E. Libman of New York said that he thought an advantage might be gained by using combined intravenous and intraspinous treatment even in mild cases. He recently had seen a small group of cases where there was panophthalmia and the eyesight was lost. He was sorry that he had not used the intravenous treatment.

Dr. Augustus Wadsworth of the New York State Board of Health said that there was great variation in the potency of the sera produced by different laboratories. It was important for the physician to know what was the potency of the serum he was using as regards agglutinin reactions and the complement fixation test. The only complete statistics were those of the Rockefeller Institute. They kept in touch with the distribution of the serum and the clinician who used it and received reports on all cases. In the literature generally there was no knowledge of the serum used. Commercial sera were not very potent. They were now attempting to produce more potent sera, but there was no exact record of its strength. The regulations required that the potency of the serum be recorded. This was brought about by the action of the Public Health Council through Dr. Biggs. This ought to be borne in mind and more significance attached to the results of sera used.

Major Litchfield, M.R.C., Camp Upton, said they had taken very early to the use of the intravenous injections in all cases. They had a very good man for intravenous and intraspinous work, and he had never had an accident. Slight anaphylaxis had been seen in one case, but it disappeared. Young men were apt to be overconfident when they had given many injections without ill effects being seen, but with the growth of the antipneumococcus and antimeningococcus therapy trouble would be met with and accidents would occur again and again if desensitization was not done. In one case 45 c.c. were given without effect, then 60 c.c. were given intravenously in 20 minutes with very serious result. The method was good and efficient, and in the next 12 months many young men would have to be trained to its use. It was impossible to overemphasize the necessity for caution against accident, no matter how long a series of safe cases had been handled.

Dr. Simon Flexner said, in closing, that in regard to civil practice he would advocate applying the principles taught by military practice. It was a matter for judgment and to where the best point of attack against the disease should be. When there was meningeal involvement the combined treatment could be used for the time being. Dr. Amoss was careful to state that there was a great difference in the treatment of monkeys and of human beings in regard to the meningococcus infection. This was very different to the effect of

poliomyelitis in the monkey. The extent to which antibodies might pass from the general circulation to the choroid was an important question. In reply to Dr. Meltzer he would say that Dr. Amoss had spoken of the meningochoroid complex, not alone of the choroid as having affected permeability. Once the meninges were injured the antibodies could pass through the choroid, and bacteria also. With the meningococcus the position was worse than the pneumococcus for determining the infectious power and the amount of antibodies. Such overwhelming doses had to be given to animals before one could say that the serum had prevented death. In pneumococcus infection one could produce an infection which gave a measure of the infection. One was very far from knowing how to measure antimodies correctly, but one had to use any test that would bring out the important point of specificity. If the organisms produced disease, one had to counteract them. The only test showing specificity was agglutination, so that that method was the one to use at present.

Major W. W. Herrick, in closing, said it was important to keep in mind any focus of infection in the body. The meninges formed such a focus, also the pericardium. In cases developing pericarditis the meningococcus was isolated in pure culture. The intravenous treatment cleared up the picture entirely. The same was true of panophthalmia. The intraspinous method was used when the meningitis was established. The subcutaneous method was used on infants. Dr. Meltzer asked how the epidemic terminated. It had not terminated. The cold weather drove the men indoors into crowded quarters and infection easily spread. In regard to potency of the serum physicians should know the type and potency of the serum used. The serum was furnished by the government, but it was commercial in origin. It was of one type. Several types were necessary so that if the case failed to respond to one it might be changed quickly to another. The price should be standardized. In South Carolina $6 was charged for 30 c.c. serum, which put it out of the reach of the poorer patients. This matter should be taken up by the government. Major Litchfield's advice as to care in injections was very timely. They had abolished the syringe and installed a device for giving 1 c.c. per minute. In this way accident could be avoided.

Captain H. Amoss, M.R.C., in conclusion, said that they had tried to study cases as completely as possible. No differences could be detected except in agglutinating properties of the strains. It was dangerous to draw conclusions on effects on young guinea pigs. Serum A was a serum standardized by complement fixation. Serum B was standardized by agglutination. There was a great difference in the therapeutic effects.

Myrtol and Eucalyptol Poisoning.—Dr. Lewellys F. Barker of Baltimore made this report. In view of the fact that myrtol, a preparation closely allied to eucalyptol, was used in treatment of putrid bronchitis, it was worth while to mention that symptoms of poisoning had been recorded from these preparations. Myrtol and eucalyptol were derivatives of myrtaceous plants. Eucalyptol poisoning had followed both overdoses and small doses of the drug, and it appeared that some persons might have an idiosyncrasy to it. Two different syndromes were noted in the after effects—first, nervous system involvement with collapse; second, dermatitis. In the nervous type the patient became seriously ill shortly after the dose. Vomiting, diarrhoea and coma might follow. Vomiting should be induced to prevent further absorption of the poison. Skin lesions were often associated with the nervous lesions. Several fatalities had been reported from time to time. A greatly increased use of eucalyptol had resulted from its employment as a solvent for the Dakin solution, dichloramin-T. It would be interesting to know if any ill effects had been observed from its use.

Dr. Flexner said that Dr. Dakin and Dr. Dunham had discontinued its use on account of irritating properties. They were now using paraffin as a solvent.

Clinical Aspects of Peptic Ulcer with Special Reference to Roentgen-Ray Diagnosis.—Drs. J. Friedenwald and F. H. Baetjer of New York presented this subject. Seven hundred and fifty-three cases were studied by the *x*-ray. They were examined first clinically and then sent for *x*-ray examination, without note of clinical findings, to see how closely the *x*-ray findings corresponded. There were three groups of cases: (1) Those operated upon and where the diagnosis was proved; (2) Cases with positive *x*-ray and clinical signs; (3) doubtful cases. It was found that duodenal ulcer was easier to diagnose than gastric ulcer. The functional signs were important for diagnosis, a hyperactivity indicating presence of an ulcer. Complications, such as abdominal adhesions, were apt to mask the findings, and the clinical history must be considered before making diagnosis. On the other hand, the *x*-ray would often clear up misleading clinical signs. In the differentiation between gastric ulcer and malignant conditions the clinical history had to be carefully weighed. Indurated ulcer often tended to become malignant, but a microscopical examination at operation was necessary to clear up the diagnosis. If *x*-ray signs were absent it was a good reason for excluding ulcer from the diagnosis. It was shown by the *x*-ray that a long time of complete rest was necessary in order that the ulcer might heal.

Dr. L. F. Barker of Baltimore said that in regard to the motility of the stomach as shown by the *x*-ray they always made it a rule at an examination to have plates taken at short intervals, so as to get a better idea of the gastric function. It was difficult to make a diagnosis between pyloric obstruction and malignancy. Other evidence was needed besides the *x*-ray. A laparotomy was often necessary.

Dr. T. R. Brown of Baltimore said that the fluoroscopic examination of the stomach was the ideal method. The series of pictures showed the exact function of the stomach. He had used the fluroscope in ten thousand cases. The percentage of correct diagnoses was as great as with the *x*-ray. The majority of Roentgenologists depended more and more upon the fluoroscope. In regard to hypermotility, the fact was not generally recognized that this was somewhat paradoxical. There was hypermotility at first and retention toward the very end. There was a differentiation between the hypomotility with patent pylorus which was usually seen in early cases of malignant disease. It was not often recognized how many of these cases were due to visceroptosis. The symptoms accompanying the constant drag on the viscera were apt to simulate gastric ulcer.

Dr. B. W. Sippy of Chicago said that in using the *x*-ray they must not forget other important means of diagnosis. The *x*-ray was very convincing, and explained a lot of mistakes. If one studied the case carefully with regard to the pain and other symptoms one got evidence every bit as important as that afforded by the *x*-ray. The *x*-ray was valuable as confirmatory evidence, but it seldom gave evidence that one could not get before by other means.

Dr. F. H. Baetjer said that the roentgenographic diagnosis was in accordance with the clinical findings in 75 per cent. of cases. It ought to agree up to 100 per cent. It was one of the many laboratory methods in use and with all laboratory methods a proper consideration of the history of the case was necessary. All evidence must be given due weight and correlated. The adhesions of chronic appendicitis often gave confusing symptoms. The reflex activity of the stomach from other conditions could not be ruled out. The stomach could not be considered as a fixed organ. It was variable as to its position and motility. What was *normal for the individual* must be considered. A man weighing 160 lb. had a stomach high up in the diaphragm. A person of 100 lb. had a fish-hook stomach working against gravity. A stomach of this type took longer to empty. Thus the *x*-ray could never give exact findings of the stomach as it could of fixed organs. Dr. Sippy's point was a timely one. Diagnoses could not be made from *x*-ray findings alone, but from all other clinical signs.

The Healing of Peptic Ulcer.—Dr. B. W. Sippy of Chicago read this paper. The protection of the ulcer from the digestive action of the gastric juice by hourly feedings and the early giving of alkalies, formed the basis of the treatment outlined. This treatment had been applied to 2000 cases, of varying duration from one month to thirty years. The average duration was four years. The ulcers were of varying degree of penetration. The ulcer healed rapidly by cicatrization. It could be said that operative procedures had a definite mortality which weighed against this method of treat-

ment. Therefore, unless the cases were operated upon healing must take place. Three points were connected with the healing of ulcers: (1) What were the causes of ulcer? (2) What prevented the healing of ulcers? (3) What could be done to heal ulcers? By answering these questions one could arrange a rational method of treatment. First, as to cause, the mucous membrane of the stomach, from lowered resistance (perhaps vascular or perhaps from bacterial invasion) became digested and an ulcer was formed. Pepsin had a solvent action on albumin sensitized by free acid. In ulcer, therefore, it was necessary to destroy the digestive action of the juice. This could be done by the method outlined. In pyloric obstruction 90 per cent. of cases had been relieved in from one to three weeks.

Dr. J. FRIEDENWALD of New York said that he had used this method of Dr. Sippy's a great many times and had found it exceedingly valuable. It had given better results than any other line of treatment.

The Comparative Food Value of Protein, Fat, and Alcohol in Diabetes Mellitus as Measured by the Nitrogen Equilibrium.—Dr. H. O. MOSENTHAL of Baltimore read this paper. It was desired to maintain the protein tissue in spite of using a carbohydrate free diet. The patient was put upon 1000 calories with a constant proportion of protein and fat. Then 500 calories of protein fat or alcohol were added. Three periods were used: fat period, alcohol period, protein period. Finally there was a control period. On 1000 calories diet there was a constant loss of nitrogen. Plus 500 calories of fat there was no great improvement in the nitrogen balance. The fat was assimilated, but did not spare the protein. The same held true with alcohol. The alcohol possibly saved the body fat, but not the nitrogen. The results with protein addition were strikingly different. The positive nitrogen balance was very marked indeed with 1500 calories. There was thus opened up a method of therapeutic treatment for these patients, which seemed to be brought about in some way which did not occur in the ordinary individual. The previous diets had evidently affected the protein. Two patients who had not taken the alcohol did not get the results. The fat and alcohol had been used to conserve the fat of the body, while the protein preserved the protein even on the protein and fat diet.

A Case of Bulimia, with Remarks on the Causal Treatment of Some Functional Diseases.—Dr. G. DOCK of St. Louis presented this report. The textbook descriptions of this condition agreed mainly upon the polyphagia. Goiter was supposed to be a factor in this condition. In the case presented the patient, an architect, aged 36, was obliged to eat abnormally to avoid intense headaches which came on when he got hungry. Apparently he had no regular eating time, but always carried with him a quantity of toasted bread cubes and six to eight shredded wheat biscuits. The history was vague. He was well until 21 years, then began to suffer from eructations of gas which he called "gastritis." At 22 had paralysis of the right arm. He now weighed 215 lb. Gland extracts had no effect on his condition. He was a large man, but with no pathological distribution of fat or hair. There was evidently a slight neurasthenic element in the case. Upon examination it was found the man had marked nasal obstruction by polyps, with suppuration of both antra and extremely bad teeth. There was a slight polycythemia. The Wassermann test was negative. The stools were very large and full of undigested fiber. Bulky vegetables were supposed to relieve the patient's hunger better than meat. In 24 hours he consumed about 7000 calories. The stomach and alimentary canal were normal, but rather large. The patient showed marked impatience with tests that interfered with his eating. No metabolic, intestinal, or pancreatic disease was discovered. The marked sinus disease suggested irritation by an impulse such as known in itching diseases. Treatment was instituted and consisted of removal of bad teeth and draining of the sinuses, which were full of foul pus. After this the headaches and abnormal appetite disappeared within one month. The patient had a normal weight and was without symptoms. It was a platitude in medical teaching that diagnosis meant covering the *whole* condition of the patient. In this case there seemed no connection between the disease and the cure; it was simply mentioned as being unusual in its course and recovery.

Dr. L. F. BARKER of Baltimore said that they had a patient in Baltimore who was known as the Raw-Eggs-at-the-Theater Lady, on account of her habit of taking raw eggs to appease her hunger during a performance. This was a frank bulimia, and she was accustomed to take quantities of food in the night. He had not heard whether she was ever cured or not. It was an interesting case of perversion of an instinct. He had come to the conclusion that it was a central nervous disturbance, just as was chewing of the finger nails. He thought in the woman's case there was a psychoneurotic complex. He would like to emphasize the importance of Dr. Dock's concluding statements as to the importance of making an examination of the *whole* patient. Often neurotic symptoms would clear up upon removal local irritating causes. Whether in this case the effect was due to clearing up of infection, or to the rather strongly suggestive psychic influence of the removal of teeth and sinuses, which was quite a marked therapeutic performance, would be hard to say. He had noted the case of an Anzac, returning from Washington. The man had been two years blind, and now saw for the first time. He was looking out of the window and exclaiming at everything he saw. He was asked how he happened to regain his sight. He said he had been examined everywhere by specialists, and had spoken of a pain in his neck of which they took no notice. He had gone to Washington and a doctor examined his spinal vertebræ and found one in the neck displaced. The vertebra was jerked into place and the man immediately began to see. Evidently psychic suggestion played a very strong part in some cures.

Dr. WARREN COLEMAN of New York asked what proportion of the food ingested was utilized in metabolism. Was an examination of the stool made? Another point was whether the absorption of the toxin produced by the infecting organism in the sinus might not have increased metabolism to a point where most of the food was utilized.

Dr. G. DOCK, in closing, said that he was not able to make complete observations due to the complete change in the aspect of the case after treatment of the sinus. The man's weight had dropped from 215 to 175 pounds. There was a slight over nutrition before. There was a great deal of undigested fibrous material in the stools, as those of animals.

The Fractional Examination of the Duodenal Contents.—Dr. M. EINHORN of New York reported this subject. The duodenum, it was stated, played an important rôle, both physiologically and clinically. In this organ the acid contents of the stomach became alkaline. The duodenal juice was studied with regard to alkalinity: (1) In patients under duodenal alimentation; (2) in patients who had duodenal instillation with water. The tubes being already in place, the examinations were easily made. Fluid food was used. this being beef bouillon. Thirty-two persons were examined. Fasting duodenal contents were aspirated. Beef bouillon was then introduced and the contents aspirated again. The degree of alkalinity and the amount of amylopsin and trypsin were examined. Cases were graded according to acidity. It was supposed that alkalinity would be less with hyperacidity of the stomach, but this did not hold good. The duodenal juice should be of importance, as the pancreatic juice was dependent on an alkaline medium for its activity. In some cases the change did not take place as well as it should do. It was found best to examine the duodenal contents for bile, with a fasting stomach; for pancreatic activity it was best to study it after a meal.

The Relation of War Wounds to Acute Endocarditis.—Dr. H. T. KARSNER of Cleveland made this report. The incidence of acute endocarditis following wounds of the war justified calling attention to its bearing on pathology, clinical medicine and surgery. In France, during the early months of the war, the surgery was such as is seen in civil life. The great contamination of war wounds was not sufficiently considered. In eight months' experience Dr. Karsner said he performed autopsies on all deaths (eighty-eight in number) occurring in a military hospital. At first they were handicapped by lack of laboratory facilities, but later exact measurements were taken of the weight of organs. Fourteen cases of the eighty-eight showed lesions of

acute endocarditis following septicemia and pyaemia. The organisms responsible were mostly streptococci. Three showed *Staphylococcus aureus*. In one case the perfringans was found in the blood stream at death. These infections followed multiple extensive wounds, not of any particular type, but in cases where an attempt was made to save the injured parts and where the wound was allowed to drain pus for weeks and weeks. In the effort to save the joint extensive damage was done to the heart and kidneys. In the later months of the war an effort was made to determine whether the age of the soldier and the length of his term of service had any influence on these conditions. It was found that if the man was less than 27 years of age and had less than 22 months' service, the kidney weight and the heart weight were normal. The principal factor seemed to be the length of service, prolonged service leading to a great increase in the weight of the heart.

Dr. W. W. Ford of Baltimore said he would like to call attention to one point. In experimental work with the gas bacillus there was a failure of the organism to multiply in the blood stream, but if one introduced a young culture into rabbits or guinea pigs the animals died. Rapid multiplication of the organism was found at the site of inoculation. Smears of the blood of heart, liver or kidneys showed a gram +, encapsulated organism, or the gas-bacillus. No multiplication was found in the blood stream. The organism was anerobic and multiplied at the site of inoculation.

Dr. T. McCrae of Philadelphia said this was a very important communication. It had an evident bearing on the treatment of the condition. If there was involvement of the aortic valve it was easy to decide that there was endocarditis. Mitral endocarditis was very difficult to diagnose. Embolic phenomena should be looked for and would confirm diagnosis in a number of doubtful cases.

Trench Fever.—Dr. Eugene L. Opie of St. Louis read this paper, the result of studies by himself and Drs. A. Strong, H. F. Swift, W. J. MacNeal and A. Pappenheimer. From the beginning of the war, in 1914, and more in 1915, there had appeared outbreaks of an ill-defined fever, observed first by Graham, and named trench fever. Studies on the infectivity of the disease were convincing and it was proven capable of transmission to human beings. The disease was characterized by a sudden onset, inability to continue work, with paroxysms of fever. It was thought at first to be a modified form of typhoid in inoculated men. Pains in the limbs and skin spots occurred with the fever. The spleen became palpable and there were marked vascular disturbances. The disease might last for several weeks or months. It being supposed that the disease was transmitted by lice, experiments were made by allowing lice (which had bitten trench fever patients) to bite healthy persons. The rôle of lice had been the subject of much discussion and no steps had been taken by the British authorities to effect their extermination. Major Strong therefore obtained Red Cross funds for an investigation, and volunteers, from the American Expeditionary Force, offered themselves for experimental purposes. These men signed a paper to the effect that they were willing. This was required by the authorities. The volunteers were subjected to careful physical examination, and charts were kept for a week preceding the experiment. Careful studies of the urine and feces were made, to exclude possibility of typhoid. Two problems were studied: (1) infectivity of the blood. Of 16 men inoculated with infected whole blood 15 developed trench fever. Of five inoculated with clear plasma all contracted the disease. The corpuscles of the blood then did carry the infection. Inoculations of plasma, passed through a Berkfeldt filter, did not cause infection. Filtered virus then did not produce the disease. The inoculation period was from five to twenty days. The disease was transmitted through three generations subsequent to the first inoculation. The second problem was to determine whether lice transmitted the disease. Of 22 volunteers bitten by infected lice 14 developed the disease, 8 volunteers not bitten did not develop the fever. Lice from trench fever patients were put upon the volunteers and kept there 30 days till the fever developed. After 48 hours lice were removed from half of the volunteers and put on other volunteers, to exclude possibility of mechanical transmission, directly from patient to individual. It was proved that the virus carried the infection. The lice were put on the arm in a piece of old undershirt, so that eggs and larvae were reproduced normally, and these were strapped on, the men were allowed to scratch so that normal skin irritation was produced. The inoculation period after biting was from nineteen to twenty-five days, as compared with five or six days with the plasma infection. The conclusions from these experiments were that: (1) direct transmission was not essential; (2) if lice carried the disease measures should be taken to combat it by eradication of lice; (3) the eradication of lice, and by this means eradication of the disease, was not impracticable.

Dr. Futcher of Philadelphia said he had had an opportunity to see cases of trench fever in an English base hospital. Distressing nocturnal pain was a symptom of the disease. Sir David Bruce had conducted some experiments in the Hampstead Hospital. He found that if 500 lice that had bitten trench fever patients were allowed to bite volunteers the results were negative as far as transmission of the disease was concerned. It was not stated how long the lice had fed on trench fever patients. In discussing these experiments it was asked if the patients had been allowed to scratch and it was found that they were prevented from scratching. Another series of experiments were then started. The arms of the volunteers were scarified. The lice were allowed to bite and the bodies of the lice were rubbed into the abraded surface. In seven days the volunteers developed trench fever. The experiments, however, as far as the biting was concerned, were not so conclusive as those of Dr. Opie. It would seem possible that there might be two modes of transmission—by the bite and by the excrement of the lice getting rubbed into the abraded surface. It was found in the trenches that lice would leave the body of a trench fever patient and go to a healthy person. It was necessary to determine whether the disease was transmitted from one to another by lice or whether it was a disease of the louse itself.

Dr. E. L. Opie, in conclusion, said that he had not tried scarification experiments. It seemed to add little to the knowledge obtained by injecting whole blood, but there was obviously possibility of introducing the virus directly through the skin. The incubation period of seven days corresponded to that when whole blood was injected into the circulation.

Pneumonia in the Army Camps.—Dr. Rufus Cole of New York made this report. Experience, he said, was confined to one army camp. Dr. MacCallum had charge of the pathological work. Pneumonia among soldiers was a most serious disease, on account of its mortality, just as it was among the civil population. Experience on the Mexican border convinced the authorities of the seriousness of the condition. The past winter had shown alarming increase of pneumonia and a high incidence of measles. In studying types of pneumococci many abnormal types were encountered. At Camps Wheeler and Bowie Drs. Zinsser and Dochez found that many cases were due to streptococci. Under the direction of Colonel Russell a study was then made of all types of pneumonia. Two definite types were discovered. In the measles ward there were many cases of severe pulmonary infection. These were similar to cases seen by the pediatrician and not usually seen in adults. The picture of the patient was extremely distressing. The patients were alert mentally and extremely anxious. There was intense respiratory disturbance and deep cyanosis. The physical signs differed greatly from lobar pneumonia, there being few signs of consolidation. In cases that came to autopsy Dr. MacCallum found small hemorrhagic spots on the lungs. The alveoli were congested and contained blood. The later lesions showed small punctate areas with opaque forms resembling miliary tubercles. Purulent exudate was found in the bronchioles. This pneumonia following measles was often mistaken for miliary tuberculosis. Streptococci were found in the sputum of these patients, and shortly before death in the blood stream. The second type of the disease, in the pneumonia wards, resembled the cases seen in civil life. These cases had pneumococcus infection. The mortality was lower. There was increased prevalence of empyema. Often there was double infection. At autopsy both strepto-

cocci and pneumococci were found. Three types were distinguished at autopsy: (1) acute pneumonia, of the ordinary type; (2) bronchial interstitial pneumonia, due to streptococci; (3) interstitial broncho-pneumonia. In other camps there had been cases of streptococcus empyema without previous involvement. In regard to the spread of infection, it was of the utmost importance to know if infection spread from one man to another, or if there was a common cause. It was known that puerperal infection, wound infection, and septic sore throat, spread by direct transference. Epidemiological evidence showed that the latter infection followed the milk routes, but direct transmission could not be excluded. In the camp wards direct transmission evidently took place, as in 55 per cent. of throats streptococci were present. In the measles ward on admission 11 per cent of patients showed streptococci in the throat; after 10 days this rose to 38 per cent.; in two weeks to 60 per cent. The question now arose as to whether this form of infection was spreading into civil life and whether the streptococci were becoming more virulent to man, so that more normal persons were becoming infected.

The Serum Treatment of Lobar Pneumonia.—Major C. N. B. Camac, M.R.C., presented this subject. A marked difference existed in the pulmonary involvement in measles and in lobar pneumonia. Four hundred cases of measles were studied in hospital No. 6. There were 43 pulmonary complications with 12 deaths. One marked condition was a serositis, the lung appearing like a sponge dipped into blood. The term pneumonia could hardly be used for the pulmonary complication of measles. The colored troops were especially susceptible to this form. In the serum treatment a desensitizing dose was first given. Six hours later 50 c.c. of serum was gradually given by a holder, a syringe not being allowed. Only one case of anaphylaxis occurred. The clinical features of this treatment were: (1) Marked variations in temperature; (2) rapid recovery; (3) absence of toxic symptoms. It was not found advisable to wait for the return of the type; a polyvalent serum being used at once, and if type I was returned, type I serum was used later. The mortality was much higher in the streptococcus infection cases. It was found that the fatal cases were those that came to treatment late. These men were stevedores, husky men who did not easily complain. Therefore, an important point would seem to be early diagnosis and immediate use of serum. If cases did not respond to one type of serum they were quickly changed to another, with better results. The pneumococcus infection was a comparatively harmless disease compared with the streptococcus type. The leucocytes were not a reliable guide as to the condition. It would seem wise that an immunizing streptococcus vaccine be tried at the same time as the serum treatment. In regard to diet, the cases should receive 2000 calories of food and 3000 c.c. of water daily.

Major E. P. Jocelin, M.R.C., said that in studying the number of cases at Camp Devens it was obvious that the increase could be attributed to the arrival of 5000 negroes in the camp. The morbidity for the negroes was 20 per cent. higher than that for white troops. It was noted that there was a great prevalence among the officers of hemolytic streptococci. Seventy-one per cent. of the officers and 62 per cent. of the nurses showed positive throat cultures of this organism. The question arose whether to protect the patients against the officers or the officers against the patients. During April 66 negroes came into hospital with pneumonia; the mortality was 14 per cent. before that; later it rose to 25 per cent. There were no fatal cases of type I pneumonia. In all the cases of negroes autopsied lobar pneumonia was found.

Major H. Brooks, M.R.C., said that when he heard colored troops were going to Camp Devens he said that trouble was coming to Major Jocelin in the shape of a black cloud. One colored regiment had furnished more patients than 77 white divisions. He was glad Dr. Cole brought out the point about the incidence of measles and pneumonia and the type dealt with. They had also had streptococcus pneumonia, but it was not connected with measles. As regards serum treatment, it would seem as specific as the use of mercury in syphilis. The symptoms of the disease disappeared with startling rapidity. Analysis of 100 cases showed that the patients were worse for polyvalent serum. They were then given type I serum. Dr. MacCallum's work on interstitial lesions was worthy of praise.

Dr. A. Wadsworth of the New York State Health Department said that he had studied the effect of different organisms with the pneumococcus, experimentally, in the rabbit and dog. There was a difference in the progress of the lesion induced by pneumococci and that by streptococci. The induction of a true exudative type of lesion followed by complete recovery in the lung tissue and complete disappearance of the organism was seen in the former case. Following the introduction of large numbers of pneumococci and streptococci in many instances there was considerable destruction of tissue. In old pathological specimens kept at the P. & S. Dr. Wadsworth was able to demonstrate streptococci, even after so many years. The lesions of the pneumococcus type resolved, irrespective of the type of lesion. With other organisms introduced, such as streptococci, there was infiltration of the cells of the air spaces and inflammatory reaction in the lymphatics of the bronchus, as commonly seen in the experimental pneumococcus lesion, but the lesion went on further to progressive suppuration and organization.

Colonel F. F. Russell of Ancon, C. Z., said that there was a great difference in the type of pneumonia at the cantonments, depending upon the source from which the men were mobilized. In Boston, New York, Philadelphia, and Chicago, the men had had their measles. Men from the country districts of the South had not had measles, and were susceptible to it. Where measles began streptococcus pneumonia followed. There was a fundamental difference between these camps. There was also a difference between open camps and closed camps. In some camps men had remained without any shifting, but in some camps new men were continually coming in and bringing measles. These camps had a high pneumonia rate. Streptococcus pneumonia followed other conditions than measles. It had been described for years. The men who knew about it were pediatricians and doctors of contagious hospitals. It was the problem now to prevent the repetition of this year's work. One need not go to army camps to study the disease; it was found anywhere where measles was found, but the study of its prevention received a new incentive in the army camps.

Major W. Herrick said that they had had hundreds of cases at Camp Jackson. They found that the measles cases were extremely susceptible to cold. They had tried indoor and outdoor treatment and found that it was best to keep these cases in an even temperature, with beds carefully screened. The cough must be thoroughly controlled, and under these conditions a very much lower percentage of streptococcus pneumonia followed.

Dr. Rufus Cole, in conclusion, said that an alarming fact was that the streptococcus form of the disease was spreading to the civil population. There were probably many types of hemolytic streptococci, but at the present time differentiation was impossible. There was no doubt of the significance of the studies made at Camp San Antonio. Whether the men were getting more susceptible to the disease was one of the many problems to solve.

Major C. N. B. Camac said that Major Herrick had referred to the sensitiveness of measles patients to cold. They were exquisitely sensitive. The slightest exposure to cold was followed by pneumonia. The treatment should be in direct contrast to that of lobar pneumonia, where the patients were put into the air as soon as possible. The head to foot arrangement of the beds with sheets between to prevent infection was the best mode of disposal. It was found that if Dichloramin-T be used for a throat spray there were very few pulmonary complications. The process of infection seemed to be from above down and seemed to run like wild fire through the respiratory passages. If it could be controlled in the throat it was not so likely to spread downwards.

Antiscorbutics and Intravenous Therapy for Scurvy.—Dr. Alfred F. Hess of New York made this report. He emphasized the necessity of antiscorbutics in any diet. In ships in the days of sailing vessels and prolonged voyages there were always cases of scurvy. The

civil population was also dependent upon antiscorbutics in the food, and it was not always realized how narrow the margin of safety was. In Ireland, when the potato crop failed, scurvy at once appeared. From the military point of view antiscorbutics were important. In Russia, during the war, there had been thousands of scurvy cases. In France, in one sector, of 1000 men 850 had scurvy. If the war kept on this might assume serious aspects, and it was necessary to consider what were antiscorbutic foods. Experiments showed that dried vegetables soon lost antiscorbutic properties. Orange juice, if preserved, also lost this property. Orange peel, which was a waste product, seemed to have the property of staying antiscorbutics in action. Its use in asylums where the price of oranges made their use prohibitive would be an economic measure. It was found also that boiled orange juice, given in intravenous injection, acted like a charm in scurvy. Scurvy could be absolutely controlled by giving heated and neutralized orange juice intravenously on a large scale.

The Thyroid Hormone and Its Relation to Metabolism.—Mr. E. C. KENDALL presented this report. A definite chemical substance had been isolated from the thyroid gland, containing 60 per cent. iodine. This was found to have a marked effect on cretinism and myxedema. The substance existed in two forms, an amino group and an acetyl group, which bore to each other the same relation as kreatin did to kreatinin. In the myxedema patient the metabolism was 40 per cent. below normal and could be increased to normal by the injection of this hormone. The iodine content of the hormone did not enter into its action but merely increased the reactivity of the functionating groups.

Studies on Some Unusual Types of Diarrhea.—Dr. T. R. BROWN of Baltimore made this report. The mechanism of normal peristalsis, he stated, was easily disturbed. Vasomotor abnormalities, abnormal substances, psychic stimuli, etc., were all causes of diarrhea. Diarrheas were of many kinds—gastroenterogenous, achylic, of Graves' disease, of tabes, of sprue, of cholecystitis. In the thyreogenous diarrhea the nervous syndrome was the cause. In the diarrhea after cholecystectomy the stools showed absence of trypsin and diastase. They were pancreatogenous in origin. Gastric diarrheas were not. In tabes there was the true neurogenic type. In sprue there was no trypsin or diastase in the stools; pancreatin could be given with good result. In appendicitis and colitis there were probably erosions of the mucosa, due to bacterial infection. Open drainage for three months would cure these cases by changing the bacteria of the lower valve from anaerobic to aerobic.

Dr. H. S. PLUMER of Rochester, Minn., said Dr. Brown had referred to diarrhea in Graves' disease. Was there no other symptom?

Dr. BROWN said that intestinal symptoms occurred later.

Remarks on Chronic Septicemic Endocarditis with Splenomegaly; Its Treatment by Splenomegaly.—Dr. D. RIESMAN of Philadelphia presented this paper. Patients in this disease might become bacteria free and yet succumb. The cases did not all, however, terminate fatally. The symptoms often included anemia, joint pains, albuminuria, nephritis, abdominal pain, heart murmur. The spleen was always enlarged and obscured the underlying heart effect. The disease might be mistaken for splenic anemia. The accumulation of bacteria in the spleen often prevented the cure of the disease. If this focus could be controlled the heart lesion might be improved, In the case of a man 57 years of age, in whom Dr. Deaver removed the spleen, the condition cleared up wonderfully after operation. It was possible that this operation might be of similar help in other cases.

Dr. E. LIBMAN of New York asked if the blood culture was positive in that case. These patients showed an enlarged spleen with the acute streptococcus endocarditis. The spleen in these cases was large and soft. The blood picture was that of a spontaneous freedom from bacteria. There was a low white blood cell count with many lymphocytes, with total decrease in the large mononuclears. The spleen had sometimes been removed under the wrong diagnosis. He had never thought of performing this operation in the bacteria free stage. The patients usually became more anemic and he wondered what the anemia was from. There was continuous infection of the spleen and in the bone marrow. It might be of use to remove the spleen in such cases. There was the same picture in progressive anemia, even without the large spleen.

Dr. Riesman said the blood culture was negative.

The General Theory of Clinical Diagnosis, with Special Reference to the Application of a Key Principle to Major Groups of Mental Disease.—Dr. E. E. SOUTHARD of Boston presented this subject. He said that books on medical logic were dust covered, or even remained with pages uncut. The question of "what is diagnosis" was rarely considered. There were various methods of diagnosis and different factors, such as inspection, and type matching formed part of these methods. Other forms, such as diagnosis by exclusion, were used, and the form called "ex javantibus" that was to treat the patient for syphilis, and if he got well to say that he had syphilis, was often in use. In mental disease type matching was impossible as any symptoms of mental disease would match all forms of mental disease; in other words, there was no indicator. In regard to exclusion, every mental case deserved to be tested for syphilis. This should be excluded if possible. In most mental diseases there was no difference in treatment, and therefore not much use in differentiating the disease. About 15 per cent of mental disease was due to syphilis. Some sort of pragmatical scheme for orderly arrangement in diagnosis should be followed, first observation, then comparison, then exclusion, then addition of statistical data. This method was largely neglected in the textbooks and even in class A schools.

Dr. L. F. BARKER of Baltimore said that this was a most interesting subject and should be thoroughly discussed. The speaker had urged a pragmatical method. It was necessary to start from the pragmatical standpoint. The end in view was that of therapy, but there were many other aspects. The Rockefeller Institute had quite other ends than that of therapy and where the profession stopped, they began. The diagnosis per exclusionem was not complete if it did not take in the psychiatric field. There was only one real diagnosis and that was one which considered the patient as a *whole*. The somatic, psychic, and all other systems must be considered. The steps in diagnosis were briefly (1) feeling of a difficulty; (2) suspension of judgment until evidence was collected; (3) making of an anamnesis; (4) laboratory tests; *x*-ray tests. All this should be done before thinking of the diagnosis. The whole man should be studied and then the data arranged in order to stimulate suggestion. The different systems would be next considered—cardiovascular, nervous, alimentary, etc. The mind could now range over facts and leap to certain conclusions. Experience and intuition would play a part in these leaps. Then by process of deduction and reasoning the diagnostic situation could be arrived at.

Dr. G. DOCK of St. Louis said that in regard to diagnosis he once looked at a patient with cancer of the stomach and made the diagnosis. On coming away a man said to him, "I liked your diagnosis very much." Dr. Dock tried to take the compliment modestly, and he found the reason for it was that he was the first doctor who had taken the trouble to look under the patient's shirt and examine the abdomen. In regard to the Wassermann test, he did not care to have it made when it had no bearing on the diagnosis. The proportion of syphilitic cases was small. He knew of one case where the man had a 4+ Wassermann, and was considered to have tabes, yet he died of a spinal cord tumor. Syphilitics might die of a different condition.

Dr. E. E. SOUTHARD, in closing, said that he would not choose diagnosis before observation, nor did he believe in choosing an hypothesis and then going to prove it. The profession were apt to overdo the analytic side and neglect the synthetic side. The naive observer often made a better diagnosis than the analytic student. In regard to Dr. Dock's point, a man with a 4+ Wassermann should be treated for syphilis, whether he had a spinal cord tumor or not. Where the Wassermann test had not been made harm was often done. There was a proportion of syphilitic cases among the mental and nervous group, at least in Massachusetts, and even if the rest of the country was cleared up it would do no harm to clean up Massachusetts.

Clinical Types of Paralysis Referable to the Pallidal System of the Corpus Striatum.—Dr. J. RAMSAY HUNT of New York read this paper. Paralysis agitans was one of the types of paralysis due to effect on the corpus striatum. Associated movements were due to effects on the strio-spinal system and disassociated movements due to the cortical system. In normal individuals these systems worked together, in pathological conditions they became disassociated. Paralysis represented this phase. There were two types of movement; in the cortical type clonus was present, in paralysis agitans it was absent. Often the two types were combined, owing to the juxtaposition of the corpus striatum to the internal capsule. Recognition of the two types of paralysis would help in diagnosis. These facts would be of importance in reeducation.

Dr. E. E. SOUTHARD of Boston said that Dr. Franz had been doing interesting work in reeducation of hemiplegiacs and had been getting results. The reeducation of hemiplegiacs had been hopeless work hitherto, but there seemed to be a glimmer of light dawning. The future outlook might be less pessimistic.

Some Preliminary Observations on Certain Phases of Hypertension.—Dr. E. S. SMITH of Boston gave this paper. The present status of the subject would show that to avoid brain disaster, hypertension must be controlled. Factors entering into normal circulation were the peripheral resistance of the vessels, the propulsion of the blood through the arteries, and the vasomotor control. Hypertension was often caused by accumulation of toxic end products of bacterial proteins. If it persisted it caused strain on the heart and cardiac fibrosis. The cases where arteriosclerosis had resulted from hypertension were different from the luetic type. In regard to treatment, attention was paid to focal infection, absolute rest was ordered, and the protein intake of the diet was limited. Digitalis was given, but no vasodilators, unless in extreme emergency.

Dr. G. DOCK of St. Louis said he was much interested in this work. He had kept from drawing conclusions. It struck him that many patients had an unnecessarily high blood pressure. Rest, regulation of diet, attention to the bowels had a marked effect on blood pressure. He did not think it necessary that pressure should be greatly lowered as long as symptoms were being relieved by mild treatment.

Dr. H. S. PLUMER of Rochester, Minn., said he thought that putting the patient in bed in the horizontal position was responsible for the change in blood pressure.

Function of the Thyroid Gland.—Dr. H. S. PLUMER of Rochester, Minn., presented this subject. He said that the composition of the thyroid was formed by relatively dormant epithelium, filled by a certain amount of colloid. The latter did not play any part. Hypertrophy was an indication that the thyroid was overstimulated and was supplying the body with too much hormone. Colloid deposit in the gland showed it was hard worked to make enough hormone. It was either normal or subnormal. The thyroid contained fetal rests and thyroid adenomata developed postnatally and were not coordinated with the needs of the body tissues. High stimulation from high metabolism would start these adenomata functioning wildly. If the adenomata were removed from the thyroid the metabolism would at once drop to normal. These cases constituted one-third of exophthalmic goiters. A metabolic laboratory had been started to carry out this work. Twenty-five cases of exophthalmic goiter were examined and it was found that the metabolism was running 1 per cent. above normal. Removal of the adenomata caused the metabolism to drop to normal ten days from operation. It was found that 1/3 mg. of thyroid was necessary to keep up the metabolic level of the body. Myxedematous cases had a metabolism of 30. These cases were given 16 mg. of Alpha thyroxin intravenously to bring the metabolism to normal. It could be said that the thyroid hormone was as fundamentally a part of the catabolic process of higher animal life as chlorophyll was of the synthetic process of vegetable life.

Dr. L. F. BARKER of Baltimore said this was an important mathematical contribution. If one could put in so many milligrams of thyroxin and produce a quantitative caloric burning effect it was an important result.

Dr. G. DOCK of St. Louis said that this work led to exact methods of thinking. The sensibility of the patient had to be considered, these hormones might show the same irregularity in the patient as other toxic substances would show.

Dr. H. S. PLUMER said that 1½ mg. of thyroxin a day was a basal rate for needs of thyroid in the tissues according to metabolism. With higher metabolism a larger amount was needed.

Therapeutic Hints.

Formalin for Warts.—Suldey advises applications of formalin for the removal of warts and especially of venereal warts. The solution of formaldehyde is applied every evening by means of a pledget of cotton or a holder. The surface should be lightly touched with the applicator, as it is advisable not to wet the surrounding skin or mucous membrane with the solution. Usually from four to ten applications suffice to effect a cure.—*Journal de Médecine et de Chirurgie Pratiques.*

Dyspepsia with Pain and Flatulence.—

℞ Strychninæ hydrochloridi.....gr. ss
Acidi hydrochlorici dil.. .....ʒiv
Glyceriti pepsini.....ʒiij
Aquæ menth. pip.....qs. ad. ʒvj

M. Sig.: Tablespoonful three times a day after meals—Williams.

Gouty Neuralgia.—

℞ Sodii salicylatis,
Antipyrinæ .....āā ʒn
Syr. zingiberis .....ʒjss
Aq. chloroformi.....q.s. ad. ʒxii

M. Sig.: Two tablespoonfuls every 15 minutes for four doses, unless the pain ceases before that time.—Williams.

Resting Varicose Veins.—Douglas H. Stewart writes in the *Medical Council:* When a person with a varicose leg goes to bed he usually sits upon the bed and draws his leg in after him. The veins of that leg are dilated and remain more or less so for hours, therefore the vein walls do not rest. Let that person go to bed, hoist his feet up in the air, the higher the better, let him keep them there for five minutes and let him lower them slowly to the recumbent position. The veins are empty and the vein walls rest. After a few weeks of this exercise many patients declare that their whole sleep is more restful.

Cinnamon Oil in Influenza.—Oil of cinnamon has a very favorable effect on the temperature, and shortens the convalescence period. Patients who usually suffer from marked asthenia for several days after an attack of influenza regain their strength very rapidly when treated with cinnamon oil, and are able to take up their occupations on the second or third day. Twelve drops of the oil are given in half a tumblerful of water, and the dose is repeated in one hour, then ten drops are given regularly every two hours until the temperature has dropped to normal. When apyrexia is complete ten drops should be given three times a day during the following 24 or 48 hours. When influenza is thus treated from the very outset, that is, within the first three or four hours, the temperature becomes normal within 12 hours; if the treatment is begun later, it may require 24 or 36 hours to obtain this result.—*Medical Press.*

MODERN STANDARDS IN ABNORMAL OBSTETRIC CASES AND THEIR TREATMENT.*

By J. W. MARKOE, M.D.,

NEW YORK.

It is befitting that those of us who have not been called for active military service should make a concerted effort to do our part for the betterment of humanity, improving our methods and leaving no stone unturned that will minimize morbidity and mortality, especially among women and children.

Much has already been done by individuals, but the mass of the profession has not as yet awakened to its necessity. Women, in the great majority of cases, are delivered of their children by the general practitioner or midwife and the present mortality of obstetrics in this country rests upon them. Therefore we must endeavor to seek out the weak points and if possible provide a remedy. Never was there a more opportune time than the present for men, especially men in the medical profession, to redeem themselves. The shock of this stupendous war has changed the outlook. I cannot better express this change than by quoting from a most admirable editorial in the New York Tribune. "Probably never before in history, not even in the Reformation or in the revolutions of the eighteenth century has there been such a general sifting out of the useless, the wornout, the harmful, as is now going in and must follow this general shaking up of present civilization. We are indeed approaching a new age and all that enters into the future must pass the severest test of social fitness. Customs, practices, beliefs which have survived for centuries are being broken up and cast aside by the hand of necessity. Old standards of values have fallen and new ones are being raised up."

Shall we not seize this opportunity to remold the old standards which have fallen and raise up new ones which will tend to eliminate the useless, retire the wornout, and so shame the harmful by our very honesty of character and purpose that they will gladly join in the general transition?

Surgery and most of the special branches of medicine have made great strides, but to obstetrics there remains the stigma in the minds of the laity that it is really not an important branch of medicine but rather deals with a procedure that in the majority of cases terminates naturally and normally with but a slight risk to mother or child.

*Read before the Buffalo Medical Society at Buffalo, April 17, 1918.

In the olden days the feature that delayed progress in this branch was the almost fanatical modesty that prevented any male being present at a confinement. Happily this no longer exists to any great extent for gradually the general practitioner has assumed more and more of this work augmented by the few specialists that have developed, more especially in the cities.

The pendulum that relegated the general or family practitioner a secondary place has not swung so far that there does not remain a preponderance of them in the profession. Notwithstanding the great number of maternity hospitals and charities that have developed in the past twenty years with their output of specially trained obstetricians, the fact remains that the vast majority of confinements in this country are conducted by the general practitioner with the midwife, which includes in the country districts the kindly female neighbor, a close second. The ideal plan would provide a competent graduate in medicine to conduct each confinement with expert obstetricians within call for the complicated cases, but such a condition is at present far too utopian.

My object, therefore, in presenting this paper is to impress upon all of you the short-comings that should be remedied. Before taking up the study of abnormal cases let us see what are the most frequent causes of deaths in obstetrics. Harrar showed in 100,000 confinements at the Lying-In Hospital that of the deaths occurring among postpartum admissions and the emergency labors handled by a succession of midwives and doctors before admission to the hospital, a considerably more than one-third were from puerperal infection; the next greatest cause of death was eclampsia; third, peritonitis after cesarean section; fourth, rupture of the uterus, and fifth, placenta previa. Deaths from other causes were comparatively few and comprised for the most part of causes that were not directly a part of the confinement, such as tuberculosis, chronic nephritis, heart disease, etc.

Thus we see that puerperal infection leads the fatal list and we all know that in almost every instance such infection is preventable as it is due to surgical uncleanliness and furthermore, the figures given by others show that the midwives are by no means the only ones whose cases develop sepsis. Therefore it is imperative that we medical men exert our full energy to the betterment of this alarming condition of affairs.

Eclampsia mortality is being rapidly reduced of late by the more thorough investigation of the prenatal condition of the mother, together with the improved methods of treatment.

In regard to the third most fatal cause, death following cesarean section, little can be said, but time will undoubtedly show that the great number of cesareans at present performed will, as the ultimate results are better known, be reduced to those cases in which it is really indicated and which we all know are comparatively few.

Placenta previa together with accidental and concealed hemorrhage are fortunately rare, for the mortality in these cases under the ordinary circumstances is hard to combat, coming as it does in the majority of cases, without warning. Therefore the most expert treatment is called for and this especially in rural localities, is not always available. We must in every way try to instill into the minds of those who are not finished obstetricians the necessity of absolute surgical cleanliness in everything.

We have seen from the foregoing statistics that puerperal infection is the main cause of death, so only by carrying out rigid aseptic methods can we eradicate the inexcusably high mortality that exists. It is a pity that the general practitioner has not as a rule had enough up to date surgical experience to appreciate how difficult it is to prevent infection from taking place; he does not realize that killing the bacteria and spores in the materials to be used in and about surgical wounds is a difficult procedure.

The different forms of pyrogenic bacteria that the obstetrician must guard against are in most cases the Streptococcus and Staphlococcus which vary in their virulance according to the surroundings into which they are introduced.

It is quite possible to find many different forms of pyrogenic bacteria in a healthy vagina without any sign of infection just as it is possible to find in the mouth and nose of a healthy human being the pneumococcus or other virulent bacteria, but this does not excuse us from making every effort to prevent the introduction of these into any field where they may at any moment become virulent.

The normal secretion of the vagina is bactericidal, but one never knows when it is normal and it is therefore necessary for the safety of the patient not to take any chance of introducing any form of pathogenic organism.

Every physician can secure a receptacle such as a clean fish boiler, filling it with clean water containing carbonate of soda—two teaspoonsful to the quart of water—and boiling his instruments therein for not less than fifteen minutes, and better for twenty-five minutes. Sheets and dressings must be sterilized by live steam for a period of not less than twenty-five minutes, and to be more certain of its completeness this should be repeated within a few hours so as to insure that all bacteria have been killed. Special appliances for these procedures are sold in all cities but much can be done, if the principle be thoroughly understood, with an improvised apparatus.

The hands and clothing of the accoucheur must receive most careful attention—the hands especially are difficult to make surgically clean. Rubber gloves are of course a great help, but they cannot always be secured. Careful washing for ten minutes followed by bichloride solution 1-5000, or some similar solution, will be necessary.

We all know that many cases treated without any regard to sterilization recover without one sign of infection; this fact has been the great reason for unwarranted carelessness among some of the profession. A man will boast that he has had one hundred cases, but this is a very small number and he may at any moment find that he has a series of fatal or serious cases of puerperal infection due entirely to his neglect. I use the word neglect advisedly, for in the past many of the shortcomings of the nation have been due to the fact that men have attempted to perform duties for which they were not prepared. This has been seen in the automobile chauffeur; hundreds of men gave up driving horses and similar occupations to become chauffeurs without being trained. The number of accidents in consequence compelled the authorities to make stringent laws so that only those who pass a rigid examination are given the privilege of driving cars and severe penalties are imposed for failure to live up to these laws. The moral law should be sufficient for us in the honorable profession of medicine.

I believe that when our men return from the front, where it has been shown that absolute accuracy is essential not only in the trenches but in the hospitals, they will have a most beneficial influence in all walks of life by inspiring us not to undertake anything without first complying with the essential rules that govern it.

Let us in our special line be prepared to meet all its requirements, not only in hospital work but in our private cases. If the simple rules of surgical cleanliness were universally adopted by general practitioners, thousands of women who are now lost would be saved. With this in mind let us take up the subject of abnormal obstetric cases and their treatment. To define a normal confinement is somewhat difficult, as patients differ so much in their physical and nervous make-up that it is not always easy to say where the normal ends and the abnormal begins. The fact that the pelvis is normal and the relation to the child proportionate does not mean a normal labor.

Age and general development are of great importance in all cases, also the temperament of the patient; so the practitioner must study the case along these lines. The very young mother has, as a rule, an easier delivery than the woman who does not become pregnant until after the twenty-fifth year. Tact in helping these women at the time of their labor will save many a complication, for if they are left to their own devices they will frequently exhaust their forces in futile efforts which will necessitate interference at a time when the patient is exhausted; because of this I advocate the obstetric chair. Any good-sized rocking chair gives as good results as the more intricate chair that has been devised for this purpose. In this chair the patient is as comfortable as anyone can be who is suffering the pangs of childbirth. Its object is to bring the liquor amnii directly upon the dilating cervix. This and kindly encouragement will save both patient and doctor many weary hours of waiting.

If the pains are weak and ineffectual black coffee will often help; if they are too severe,

morphine is indicated. Pituitrin is being used at present by a great many physicians, seemingly without regard to what its actual effects are and the results have been far from beneficial; yet it is a useful drug when properly used. During the last year I was compelled to perform a hysterectomy for rupture of the uterus in four cases in each of which pituitrin had been used to the limit; in my opinion the ruptures were entirely due to the injudicious use of this drug. These women were all in the early child-bearing period of life, and although they recovered they are left without the hope of ever having other children.

Early rupture of the membranes when it occurs is a true complication, especially in primipara, and care should be taken to retain all the fluid possible. This in most instances will best be done by forcing the head into the cervix; the sitting posture brings this about better than anything else. Bags are frequently used and do a certain amount of good, but one hesitates to teach the general practitioner to introduce a foreign body into the uterine canal for fear of infection: I therefore have not been in the habit of advocating their use. Remember that a full bladder or overloaded rectum will delay an otherwise normal delivery.

Posterior positions of the occiput, in the great majority of cases, rotate to the front if flexion be complete and the pains good. Give these cases every chance to deliver themselves, using the chair to assist the descent of the head into the pelvis and to further flexion and anterior rotation. If in a few cases the occiput remains posteriorly, one blade of the forceps can be used as a vectis, or in certain cases where the pelvis is large and the soft parts dilatable a version will perhaps be the only solution; rarely is a craniotomy necessary, and then only in neglected cases where the child is already dead.

Breech presentations are a much more serious complication than is generally believed. They usually imply some deformity in the pelvis or malposition of the uterus. In these cases preparation should always be made for operative procedure. I never undertake a breech delivery without having a medical assistant present and all instruments ready, not only for a craniotomy on the after-coming head, but also to repair any deep laceration of the cervix or perineum.

The value of a trained assistant is that he can make pressure from above the symphysis on the after-coming head and bring through the brim of a head that could not otherwise be born. This also relieves the operator from making excessive traction from below, for severe traction not infrequently causes a separation of the cervical vertebræ, with consequent nerve injury of greater or less degree.

Never rupture the membranes in a breech presentation until the last possible moment, as one needs all the dilatation possible before undertaking the extraction of the shoulders and after-coming head. The maternal mortality in these cases is not greatly in excess of that of normal cases, but the injuries to the perineum and cervix are much greater, especially if force be necessary in the delivery.

Prolapse of the cord, in either breech or any other presentation, calls for immediate action. In rare cases the cord can be replaced by the use of a stiletted catheter which you all know, but in most all such cases the cord will again prolapse immediately if the woman assume the upright position.

Shoulder presentations are fortunately rare and in most instances indicate a pelvic deformity or uterine displacement; tumors may also be a cause. Here again we must, if possible, prevent the rupture of the membranes. The question of how to deliver such cases depends upon the extent of the deformity present.

I shall not go into the extreme cases where the only operation possible is a cesarean, but refer to those cases in which a version through the bony pelvis is quite possible. There should be no delay in these cases for the woman's strength must be conserved. Do your version early before all the waters have drained away; be sure to take the same precautions to have adequate assistants and proper instruments to meet any emergency that may arise.

If the case be seen before labor has actively set in it may be possible, in a few cases, to convert it into a vertex or breech. The chair is splendidly adapted for this purpose; by pressing the knees of the patient up against the abdomen the tendency is to straighten the uterine body.

Brow and face cases are so rare that one is seldom called upon to treat them; they are supposed to be caused by an obliquity of the uterine axis—rarely by deformities in the fetus. If the child be small and the pelvis normal there will seldom be any difficulty, but where the child is large and the proportion to the pelvis snug there will be difficulty in converting it into a normal presentation.

There are innumerable variations from the text-book abnormalities that will tax the ingenuity and common sense of the accoucheur, but above all let me firmly impress upon his mind that the worst operative risks will do far better when absolute surgical cleanliness has been observed throughout than the simplest case without it.

Having taken up the surgical aspect of abnormal cases, let us look for a moment at the medical diseases that jeopardize our women.

Eclampsia, I believe I can say, leads the list of this class of cases and its mortality is high. Here antipartum care is above all things needful. The majority of eclampsia cases can be prevented by the careful study of all pregnant women at as early a stage of their pregnancy as possible. It will not do simply to examine their urine from time to time for albumin; they must be taught to live sensible lives while they have to nourish and care not only for themselves but for their unborn children. Their diet should be regulated and they must have the maximum of fresh air; regulation of the bowels goes without saying; they should report to their physician the slightest abnormal signs, such as headache or nausea, so that he may investigate the blood pressure and urine and institute immediately such remedies as will insure proper elimination from skin, bowels, and kidneys. If the patient has been seen late and eclampsia

has occurred, we have had surprising results by the use of morphine in large doses, together with washing the stomach, rectal irrigations, and the administration of castor oil.

Dr. McPherson has published several excellent articles on this subject and has shown a reduction in the mortality from 28 per cent. by the old method to less than 8 per cent. by the new.

Cases of heart disease I have treated by keeping them in the open air night and day and feeding them well, treating their symptoms with proper medication, and allowing them to continue their pregnancy and deliver themselves normally. Much better results have been obtained in this way than by inducing labor early. Tuberculosis calls for early interruption of pregnancy, also any form of cancer.

To sum it up: The general practitioner who assumes the responsibility of confinement cases needs a most certain knowledge of the technique of surgical cleanliness. He must realize that if he take charge of a woman during the greater part of her pregnancy and anything goes wrong, such as a sudden onset of eclampsia or a malpresentation, he, in the majority of cases, is responsible; also in a case of labor where there has been no other interference, he is responsible for any puerperal infection that may arise.

I believe the careful keeping of case histories is a great help to every medical man and the more carefully these histories are recorded the better the results. He is bound to go over them from time to time, and by so doing his shortcomings are brought to his notice and he will be stimulated to overcome his mistakes.

Let us all work together and do our part to put the profession on a higher standard; to do this we must extend with sincere honesty of purpose the hand of friendship and unselfish good fellowship to all.

20 West Fiftieth Street.

WAR NEUROSES IN WOMEN.

By GUSTAV F. BOEHME, JR., M.D.

NEW YORK.

PSYCHIATRIST, EDUCATIONAL CLINIC, CITY COLLEGE OF NEW YORK; CLINICAL ASSISTANT, NEW YORK NEUROLOGICAL INSTITUTE; NEUROLOGIST, WEST SIDE GERMAN DISPENSARY AND HOSPITAL.

The present war has brought to light a multitude of new problems, difficult of solution because of the multiplexities and magnitude of modern civilization. The physician and the surgeon at the front have had many opportunities to study the resultants of modern warfare, to deal with infections, with the organic results of trauma, and the psychic manifestations of war in the form of "war neuroses" and so-called "shell shock." The troop surgeon at the cantonments has had his problems with the selection of new men and the establishment of good health in slightly damaged individuals. At his side has stood the psychologist helping him to weed out the potential coward, the probable neurotic wreck, the inefficient worker.

As is usually the case when dealing with large problems, the silent sufferer at home has been forgotten in our scheme of things masculine. We have in our desire to aid democracy forgotten that democracy begins in the home where reigns that most essential arbiter of the nation's fate—a woman. To her the nation, the struggling world must turn even now for the sons and daughters of posterity who are to carry on our work. Therefore is it necessary that we consider her health, her present problems, when a son, a husband, a brother, or a sweetheart is torn from her side. We may smile at her perpetually knitting, knitting, or rolling bandages, or stopping us on street corners crying, "Only a mite for the Red Cross," but we must ask ourselves is she paying a price beyond the personal loss of those dear to her, is she suffering from war-time ills?

"War neuroses" have to date been described as strictly masculine conditions. Yet from time immemorial we have listened to the slogan "nervous women." Why not more nervous now? Do they not suffer the same or perhaps more constant and severer strains than the male sex?

The problem of war neuroses in women is to the writer's mind peculiarly an American problem. In France, England, Belgium, and Germany the conditions have been those of actual warfare, the actual defense of the home brought the issue squarely home to the women of these countries. Their's was everything to gain, to lose; their's was to fight back of their men with every encouragement possible! But in the United States this is only gradually becoming the fact. In 1916 we elected a President with the slogan, "He kept us out of war"; the posters portrayed him as a protector of the mother and the wife because he did not rush into the tremendous European melee. The war was far away from us, we did not see our part in the struggle. The Lusitania horror had apparently been glossed over; diplomatic notes gave promise of keeping us from taking up arms—we had not realized the great principle that we were to stand for. Some far-sighted individuals saw the necessity of our entering the world war, but to the majority the message was not clear, and especially was this true of our women who saw no reason why we should take an active part. We were sending money, supplies, ships. What more could Europe want of us?

Then came the insolent message of Germany, the dismissal of her unctuous, but treacherous, ambassador and the declaration of war. To the masculine mind came relief, for we find relief in action, but to the woman came the worry, the anxiety of war—and a war she saw no necessity for. One of America's noblest women (she gave a husband and a son to the cause), Mary Roberts Rinehart, says: "So I find among women who think a vast resentment against this war. Against any war. For wars are man made. And it is the women who bear sons to fight them."

She saw the draft legislation go into effect, she struggled against "her boys" enlisting, she moved Heaven and earth to prevent his going "over there." But the inexorable decrees of Mars could not be set aside, one by one her male companions, her male offspring were leaving her to think, think, think, to worry, to feel the desperation of loneliness: as Mrs. Rinehart again ably says, "A certain morbid view is inevitable. And revelations of departmental deficiencies have brought

their inevitable train of discontent. . . . To the women at home there are quiet hours with the empty places that she feels may never be filled again: and she broods."

She called upon her male protectors to ask for a dishonorable solution of the world problem, she cried for peace; peace at any price. Her letters to her soldier were bitterly complaining, to such an extent that Capt. H. George of the Tank Recruiting Station says: "Most cases of bad morale in fighting men can be traced to the attitude of their women at home. . . . Nothing takes the fighting spirit out of a man so quickly as the pitying, sneering, or whining attitude of a woman."

So essential had this attitude become that the U. S. Army had to take cognizance of these facts and move the draft camps away from their women, who visit them and disturb the tranquillity of mind that daily training, action, etc., brings to their men.

We are dealing therefore with the reactions of the sex to a violent mental trauma and the purpose here is to survey briefly the field of the neuroses and other mental disturbances produced in women by this war.

To attack the problem one first has to consider the mental and phsical make-up of the women affected. At this point let me state that the greater number of women (and here I am kinder than most lay observers) have responded nobly to the calls made upon them. They have given freely of their moneys, of their jewelry; they have worked in camps and base hospitals; they have labored night and day on Liberty Loan and other "drives," but they have in many instances consciously, in many instances subconsciously, withheld their men from their larger duties. In fewer instances they have seized the flambeau of democracy and pushed it into the hands of their males and cried, "Fight for us, fight for our right to live." However, this command is gradually becoming more urgent and the women are responding to the call.

For the purposes of this study women will be classified as:

1. Normal women; (*a*) With adequate reactions, (*b*) With inadequate and false reactions.
2. Neuropathic women.
3. Hyperthyroid types.
4. Engaged girls.
5. Newly married women.
6. Women with families; (*a*) Dependent upon their husbands, (*b*) Independent of their husbands.
7. Women at the climacteric period.
8. Aged women.
9. Pregnant women.

All of these types have been more or less affected by the war. The tremendous unrest of the industrial and social world occasioned by the struggle to some extent has upset the equilibrium of even the best balanced nervous systems. A music teacher recently told me that she could not get the responses from her female pupils that she could in the past, as she put it, "Their minds are on the war." A corsetiere stated to me that never had she found her patrons so hard to please, so irritable, "They seem to be tense with the war," she stated.

The normal woman who reacts adequately has stopped her own emotions, held in check her own desires, and then calmly reasoned out the war and its principles for herself. She realizes the great necessity for men, and has given freely of her family. She is the type exemplified so well by the better educated classes, who have sent their sons forward and then have taken up the winning of the war themselves by executive committee and productive work. Here there is no fear of the war neurosis, the only danger for these women lies in their tendency to overwork, to give more of themselves than they are able. Exhaustion neuroses are likely to be quite common among them, in fact the writer has seen these types of cases a number of times. There is nothing especially characteristic about them, except perhaps the mental state of the patients, which is either that of marked elation, or the converse, one of severe depression, due to the fact that these women feel sorely the fact that they no longer can continue their labors.

Among the majority of so-called normal women, however, the reactions have been entirely inadequate. They have not, as has been previously pointed out, been able to grasp the ultimate reasons for the war, or our part in it. To them war meant the killing of their men, and one finds such reactions as those of a prominent concert singer who made public the statement, "I would rather kill my son than see him fight." She voiced the opinion of many women in this statement. One of the early slogans of the woman suffrage workers was that had the women had the vote we would have been out of the war; in fact they claimed that had the women of the world had control the present world carnage would not have occurred. It is indeed to be gravely doubted whether this would have been the fact, for all history points to the opposite. The ancient Greek women girdled themselves with sword-belts and fought valiantly for their rights, the women of France during the Revolution were as insatiable for blood as their men, the Sioux Indian turned over his prisoners to his women for punishment, and even in this struggle the Russian women entered the fray as a "Battallion of Death." A Joan of Arc, a Molly Pitcher, a Charlotte Cushing has taken a part in every war. It is plainly to be seen that this reaction, the desire to prevent their men from going to the front had its basis in a wish fulfilment complex, a desire to retain their men, and incidentally, as women are not economically independent, the maintenance of their homes and their comforts. The last fifteen years has been one of unusual personal extravagance on the part of the female sex in this country; styles have been ornate, outlandish furs are worn in the heat of mid-summer, the merest stripling who marries must furnish his home with "period furniture," motors bring pleasures of all kinds. This, plus the loss of her supporter, was to be the loss of the so-called normal woman. The call was too powerful and the result has been a group of inadequate reactions. Various minor neuroses have developed, the majority being of a wish fulfilment, or sexual type.

Harlow Brooks and other army surgeons have been astonished by the number of cases of hyperthyroidism that have developed in the male sex

since the beginning of the war. In fact, they have been led to give up the original belief that the condition is one preeminently femine. The test, however, should rather be checking off of these cases against those developed in women during the same period and the study of the aggravation of thyroid symptoms in women who already had minor lesions before the commencement of the war. It is difficult to do this, yet the writer has been led to believe, by the study of neurotic conditions in women, that a great many women have, with the fear of losing their loved ones, with the sudden tearing from their firesides of their men folk, developed these conditions and that the old relation still exists. Modern endocrinology has pointed to the stigmata of possible thyroid dyscrasia in apparently normal men and women, the potential victims of tachycardia, exophthalmos, goiter, etc., and certainly observers in times of peace have found them more commonly amongst women. Life insurance examiners, who in times of peace can well be compared to the present recruiting surgeons, for they examine apparently normal invidividuals, have found thyroid conditions to be preeminently feminine. Not to be forgotten as a factor in this field is the relationship of these disturbances to vagosympathetic unbalance. All are agreed that this is preeminently a feminine condition, that fear, shock, worry, prolonged strains upset this delicate mechanism, and create not only neural but endocrine manifestations. The soldier must feel them all, and at times during the stress of battle must succumb to them. His women at home bear a steadier strain; they peruse each paper, each letter, for fear that unwelcome news is there; they give up unwillingly their supporters, their offspring, with the resultant neuroses, exemplified by dysglandular and vagosympatheticonic symptoms.

Engaged girls have not suffered apparently to so great an extent from neuroses due to the war. As a rule they are younger, they look upon life optimistically, they have occupations that relieve. The heroism of a soldier, the uniform, all send feelings of pride and pleasure into the hearts of the majority. Most of them have therefore reacted without neurotic manifestations. The remainder have met their problem in one of the following ways:

They have married their lover and then either sent him proudly to the front or they have married to try to beat the draft, to save him from the front, and when this failed them developed various types of neuroses of the anxiety or sexual type. The physician who lives in a community of younger people can bear witness to the women of this type who come to him for bromides, etc., anything to still their "pains," their "insomnias," to quiet them.

A second type of engaged girl has given herself up to her lover. She has indulged in excessive demonstrations of affections, in many instances given of her sexual self, and when her lover was torn from her developed all varieties of sexual neuroses. This is especially true of women of twenty-five or thirty years who have waited for marriage until their lovers should be economically able to support them. The war robbed the man of his opportunity to climb, and the woman, seeing the destruction of her air castles, has failed to respond adequately.

Newly married women have also fallen into similar classes. They either have given freely (because they felt their ability to support themselves), or else have developed all forms of minor neuroses, chiefly of the anxiety or sexual type. To them has come especially the problem of pregnancy. Knowing full well that conception might save their males for them, they have frequently been led to sexual excesses, and here is frequently added the neurosis occasioned by the lack of longed-for children, or the neurosis caused by self-reproach in, as one of my patients said, "having been so selfish for a few years of life," without offspring. They look back over their years of coitus interruptus, etc., and develop the abnormal complexes caused by these acts. I know of the instance of one woman whose husband was killed "over there," who, when the news reached her, cried out, "I killed his child," and for weeks was a complete neurotic wreck. She still moans over her "not having his child to link her to the past."

Women with families dependent upon them and their husbands have so far been spared the severe pangs of separation. Everything is being done by the government to save these men from actual warfare. They therefore have no real strain, except that of a vague anxiety hardly sufficient to create a real neurosis, but nevertheless manifesting itself in unrest and worriment.

Women with families independent of their husbands have usually given freely of their men. They take a certain pride in feeling that their children's "daddy" will bring home a name made illustrious by war-time deeds. Theirs has been a complete marital life, and while they hope and pray for their male consorts they bravely face the future, doing their bit in properly bringing up their children to be true Americans. Neuroses here are a rarity.

A sad group at the present time are the women at the climacteric period. Their sons have just attained manhood, they have labored to develop good men, they are frequently involved in mother-son complexes, they are very jealous of their daughters-in-law to be—how much more do they feel the pangs of separation by war, how tremendous is the strain upon them at this period of life added to the tremendous upheaval in the endocrine make-up! It is in this group of women that the reactions seem to be the most violent. Here develop all types of neuroses, from the simple anxiety types to the most intense dysglandular and psychotic syndromes.

To this group belong the women who cry out against "the murder of their sons," who would rather "see their sons dead" than "over there," the women who try to reach local boards by bribery, who rail against governmental methods. These are their simpler reactions. A great many more develop definite neuroses, especially if their favorite sons are taken. The only cases of true insanity the writer has seen among women as a resultant of the present war strain belong to this group. These women as a rule suffer a complex

trauma, consisting essentially of (1) the mother-son complex, (2) the support complex (I name it so for want of a better designation), (3) the natural horror for war complex of women who have borne children, and (4) the resultants of the unbalance of their neuroendocrine systems. Small wonder, therefore, that this group should furnish the greatest number of neuroses.

Truly aged women take the war calmly. They have lived their lives, they do not have the usual worries of the other ages; they find, in fact, a certain desire to see their grandsons "do their bit." Frequently they have seen the Civil or Spanish-American war, or, if not, have been brought up to believe first of all in America, which feeling unfortunately the egotistic lives of modern Americans have destroyed to a marked extent. To these gentle old souls comes no neurosis, with them there rather is a tremendous feeling of patriotism.

The problem of pregnant women is a complex one. The married woman in this state as a rule has but little worry; her man will not be taken from her if the government can prevent. The single girl, illicitly pregnant, presents a double problem, that of her unfortunate condition combined so frequently with the desire to rid herself of the conception or the knowledge of an abortion secretly and illegally performed. The Germans have solved the problem in an obnoxious way by making illegitimate pregnancy a war-time condition to be proud of. This, however, does not appeal to the Anglo-Saxon mind. Free love in any of its forms has never been a welcome institution with the English-speaking nations; therefore these unfortunately pregnant girls face all varieties of fears, all varieties of momentous decisions, and meet them as a rule inadequately. The problem is a real one to the general practitioner of medicine, for this condition exists to a far greater extent than is generally supposed. The abortion evil is growing to Gargantuan dimensions—enough so in ordinary times, but even more so in these times of war. These girls suffer all forms of neuroses, but especially all varieties of sexual and wish fulfilment complexes. This field will be a fertile one for more study on the part of gynecologists; suffice it to state that it is a very real one for the general practitioner and neurologist.

We have attempted to outline the types of women affected, and their primary reactions to the psychic trauma of war. The actual neuroses are variegated in types, but they are essentially, in the majority, anxiety and sex neuroses, or psychasthenias. They may be considered under the following headings:

1. Exhaustion neuroses due to (*a*) Overwork and overstrain in war work, (*b*) The mental and physical strain at the time of or after the departure of their sons or husbands, etc.

2. Psychasthenias due to the prolonged fear and mental strain occasioned by the departure of the male members of their families.

3. Hysteria.

4. Hyperthyroidism and hyperadrenalism.

5. Exaggerated defense reactions.

6. Neuroses of simpler type, (*a*) Sexual, (*b*) Anxiety.

7. Climacteric disturbances.

These, in a manner comparable to those among the male sex, present no essential differences from those found in civil life. The same causes are at work, only upon a larger scale, therefore the reactions are more violent and more frequent than in times of peace. Cardiac manifestations are common; pains, palpitation, tachycardias of all types exist. One patient has the precordial pains so severely after reading of Allied reverses that she is confined to bed for two to three days. Vertigo and dizziness with associated fainting spells must by this time have become a frequent cause for "emergency calls." Gastric manifestations are not so frequent, yet one woman who read an account of bayonnetting in conjunction with seeing a motion picture of our "Sammies" attacking dummies in the South developed a most intractable vomiting.

Another patient has two sons in the army; she had always been of an hysterical type. When her boys were drafted she lived in continual dread; she never gave up her children willingly; she brooded continually and was rebellious against government of all kind. One evening she went to a nearby amusement park and was startled by the explosion of a piece of fireworks; she gave a brief cry and then became deaf. Physical examination revealed no aural defect. She had a definite corneal and pharyngeal anesthesia. After being kept quiet for a few days she gradually recovered her hearing. To her was then explained the mechanism of her affliction, the deep-seated wish fulfillment complex of not wishing to hear guns as they reminded her of unpleasant memories.

The simpler sex and anxiety neuroses manifest themselves by all forms of palpitations, precordial pains, feelings of fullness about the head, insomnia, and variegated types of morbid dreads. An entire chapter might well be devoted to the study of this type of reaction.

Hyperthyroidism and hyperadrenalism present their usual picture. The writer is led to believe that at the present time they are more frequent than under normal conditions, at least so all clinical observations on his part seem to indicate. If Crile and other observers are correct in stating that a steady strain, fear, and worry are conducive to endocrine abnormalities, especially of a thyroid or suprarenal type, the woman at home is certainly a victim of these conditions. Associated therewith one finds all types of vagosympathicotonic disturbances, but so bound up is this system with the endocrine chain that the separation of the various factors in each case is the work of the medical examiner.

Women at the climacteric are especially prone to neuropsychic manifestations. These women, under the war stress, under the strain of being separated from their loved sons, present all types of pictures, from simple precordial pains, tachycardias, insomnias, etc., to actual insanity, especially of the melancholic type.

Cases of all types could be added to exemplify the various conditions described, but the cardinal point that this war is developing neuroses in the female sex is the one to be borne in mind. A po-

lice captain, a man of remarkable acuteness of thought, stated to me recently, "I think the women are going insane from the war strain." He told me of a number of instances connected with his work, and especially of a woman who feared to cross a street, "it reminded her of a trench." The observant bystander, the music teacher, the corsetiere, the police official, among the laity has therefore noted the psychic unrest, of how much greater import is it for us to try to prevent, to cure these states of mind!

Therapy.—The therapy in general is that of all neuroses. The physician must approach the problem with sympathy, sympathy with the patient, sympathy *with our cause*. He must familiarize himself with all the factors creating the world struggle and the conflicting emotions of his patient. Unfortunately the average woman has not had adequate political education, so she sees the problem of the war as a personal one and not as a national issue. Her home is threatened, and apparently for a war across the seas in which *she* sees no necessity of our taking part. It is the duty of the physician to rectify her errors of thought, to give her mental rest and the solution of her puzzle. He can then direct her overflowing energy into new channels, into Red Cross work, knitting, etc. As to knitting Mary Roberts Rinehart makes a good point when she calls it "a mental anesthetic." The danger in any of this war work on the part of the female sex is the danger of sublimation of emotions, of the improper solution of the problem. I know of instances of women knitting, in which they cry over their work, and fondle it as if it were a lost child, an absent lover, or a husband. This work should never be done except with a clear understanding of the war's justice, when it becomes truly a labor of love, not an "anesthetic for pains"; in fact, frequently the length of the yarn measures the length of the mental strain, the flow of suprarenal substance into the blood, the overflow of neural energy.

The theater, unfortunately, at the present time, offers little relief. Everywhere songs about "daddy over there," of children crying for their dear ones, maudlin war melodies greet the ear. How much better were it if these writers of lyrics would limit themselves to the songs of the type of Cohan's "Over There," or that real message to America's women, "Keep the Home Fires Burning." To advise the theater, therefore, is a risky procedure. Books are a means of therapy. A writer in the *Atlantic Monthly* once said he would prescribe "Congressional Records" for insomnia. Well can the physician choose among modern war literature messages that will help the modern woman. Empy's latest volume, Wright's "Letters to the Mother of a Soldier," Dawson's "The Father of a Soldier," are all helpful. The reading of "A Man Without a Country" restores the nationalistic desire.

Sports are not to be neglected, for the sounder the body the brighter red the blood corpuscles, the brighter the mind.

For actual disease conditions rest, glandular therapy, tonic or sedative baths, and massage are helpful. Bromides, valerianates, etc., are virtually useless. Drugs never can stop mental processes; they are valuable only in the more tremendous types of unrest, in the excitement of hyperthyroidism, etc.

Psychotherapy of all kinds is valuable. In the climacteric and sexual neuroses especially so, for here the various complexes must be cleared up. Hypnosis is useful for the treatment of the various defense reactions, the deafness, the vomiting and allied conditions.

This has been a rather sketchy picture; it had to be so because the subject is a tremendous one and because materials are not easily to be found, not because they do not exist, but because these problems are preeminently the problems of the private physician. The writer has obtained his materials in the New York Neurological Institute, in private practice in a neighborhood hard hit by the draft, and by constant questioning of women at clubs, places of business, in their homes, and at the theater. The policeman, the managers of offices, the local board physicians, have all contributed, sometimes wittingly, sometimes unwittingly, to this study.

These war neuroses exist; they are playing an important part in our national life, and the physician at home can well do "war work" in lightening the mental burden of these women. Then they, too, will feel the poet's message who sang,

"We never give, but giving get again,
There is no burden that we may not bear,
Our sweetest love is always sweetest pain,
And yet the recompense, the recompense is there."

220 Audubon Avenue.

CANCER, A DISEASE OF DEFICIENCY.*

By JOHN ROUND, L.R.C.P., L.R.C.S.,
LONDON, ENGLAND.
HONORARY PHYSICIAN, BATTERSEA GENERAL HOSPITAL.

When, from a correct general principle one develops the conclusions in special cases of its application, new surprises, for which one has not previously prepared, always make their appearance. And since the conclusions unfold, not according to the author's caprice, but after their own laws, it has often made the impression upon me that really it was not my own work which I wrote down, but merely the work of another.
Hermann Von Helmholtz.

Cancer is an adaptive response on the part of certain cells or cell groups to environmental change: we must start with the fundamental truth that every adaptive response made by cells to environmental change is the outcome of the interaction of two factors—environmental stimulus on the one hand and the cell potentiality on the other.[1]

There are groups of cells forming whole organs which are not in direct contact with the outer world and some that are in such contact.

The epithelium of which true cancer is made up is subject to three forms of influence: The Nutritional Factor, the Neighboring Cell factor, and the External World Factor. The epithelial cancer cell exhibits an abnormal capacity for assimilating nutriment and puts this nutriment to no useful purpose; therefore it becomes a menace to the well-being of its host, in other words a fungus. Now, in proportion as a cancer cell grows away from its normal relationship and ceases to be an absorbing or secreting agent, so does its malignancy increase.

*Presidential Address delivered before The New Cross Medical Society, May 9, 1918.

What are the conditions that favor the abnormal growth of epithelium?

The first authentic account of constipation as a disease and the cause of disease was written by Dr. Robert Bell of Glasgow and appeared in the *Lancet* for 1880; since then many volumes have been written and reputations made on the treatment of intestinal stasis. Other exciting causes are chemical irritation, *x*-rays, alcohol, soot, arsenic, betel nut, clay pipes, and many more forms of irritation.

The age incidence of cancer depends on the fact that at fifty or thereabouts the epithelial cells are not able to accomplish the amount of work they did in earlier years. The late Sir Jonathan Hutchinson said that cancer was a disease of old age and that everyone would get it if he or she lived long enough.

Cohnheim evolved the theory of embryonic "rests," and thought that these "rests" were able to take on active growth at about fifty years of age and so form malignant tumors, but he failed to tell us why "rests" should acquire this remarkable power of growth after so long; therefore his theory was always more picturesque than satisfying, still it must be admitted that Cohnheim's work has served a valuable purpose in leading the way for other investigators. Box believes that cancer is caused by protozoa; he finds them in all cancers. Protozoa are widely diffused throughout the world, they are very resistant, and many of them are so small that they can only be detected with difficulty.

In Uruguay and the Argentine cancer of the alimentary tract is very common, and Box thinks that this is due to eating fish, protozoa being abundant in fish. Whether the starting point be "rest" or protozoon the broad fact remains that neither of them could develop unless there were something in the blood stream favorable to its growth.

Working in the Randolf Spreckles Laboratory of the University of California Dr. Brailsford Robinson has conducted a series of experiments with anterior pituitary gland and found it has a marked influence on cancer growth.[2]

Rats which had been inoculated with Flexner-Jobling cancer were given anterior pituitrin in the form of subcutaneous injecton of tethelin and it was found that their cancers grew 100 per cent. more than those of the control animals. Research is still going on under Dr. Brailsford Robinson and further reports may be looked for; at the moment of writing it is impossible to appraise the value of his work on anterior pituitrin.

Altmann's Granules.—In nearly all tissue cells of vertebrata, granules can be demonstrated; and investigation of the cells of pathological tissues proved these granules absent in the cells of both carcinoma and sarcoma, but present in the cells of innocent tumors and in those produced by inflammatory conditions.[3] The granules are regarded as the elementary particles of life. They may be very well demonstrated in the cells of the intestinal epithelium. They are composed of protein, are thought to be formed from the nucleus, and are liable to undergo change into fibrils which tend to collect into masses near the nucleus; at other stages they tend to run together and form fat globules which may be stained with osmic acid. Granules vary in different specimens and at different stages of development in the same cell or cells. Ehrlich introduced a series of special names for granules in different stages. Granules bear some important relation to metabolic activity of the cells in which they reside. Altmann's granules are not found in squamous epithelium.[3]

It is reasonable to assume that there is both a local and a general factor in cancer; the local factor is probably a microparasite which stimulates the epithelial cells of adults to multiply in somewhat the same way as the male gamete initiates reproductive changes in the female gamete.

The general factor is an abnormal condition of the blood, dependent on poverty of vitamines and on the presence of certain unoxidized toxins absorbed from the alimentary canal which favor the development of the local factor. First of all, deficiency of vitamines in the food we eat, to which subject we shall return later; secondly, the absorption of toxic products which enter the blood as a result of altered or overtaxed intestinal mucous membrane and the reabsorption of toxins as a result of intestinal stasis, commonly called constipation. It must not be forgotten that cancer affecting some part of the alimentary canal is often the end result of old standing constipation.

There is a certain analogy existing between tuberculosis and cancer; in the former we have a well understood bacillus with a known antitoxin and a general condition of bad health which no physician or surgeon disputes. In cancer we can only presume the existence of a parasite, while we are only too familiar with the accompanying state of bad health.

Morton and Murphy exposed white mice to repeated small doses of *x*-rays from a Collidge tube and noted this treatment destroyed the major portion of the lymphoid system without causing other visible injury or prejudicing the health of the mice. Cancer was grafted into these and others which had not been exposed to the *x*-rays; it was noted that the tumors grew much more quickly in the mice whose lymphoid system was damaged than in the controls. This result goes to show that cancer develops most readily when injury has diminished the power of resistance.[4]

Unfortunately, cancer workers have divided themselves into two schools of thought; the larger school, which includes many eminent surgeons, looks only for the parasite and pending its discovery treats its cancer patients by surgical operations often heroic in their magnitude, and one at least has gone so far as to say that nothing more can be done till the parasite has been catalogued.

A comparatively small school regards cancer as purely an error of metabolism and treats it accordingly. A series of investigations into the metabolism of cancer were undertaken in Von Noorden's laboratories and the findings are of great interest, but they do not help us much with regard to the origin of cancer, most of the observations having been made on fairly advanced cases of carcinoma of the stomach.

To return to our analogy, the *Bacillus tubercu-*

losis and its tuberculin have not done away with the necessity for the constitutional treatment of tuberculosis by fresh air, good food, and the like. For similar reasons when the cancer parasite is discovered there will still be some conditions of the blood favorable to its development and others resistant. When we turn to cancer as an accomplished fact we are on firmer ground. In the cachexia of cancer we have to deal with a toxogenous disintegration of protoplasm independent of nutrition.[6] Free hydrochloric acid is absent from the stomach in most cases; in 10 to 13 per cent. it is present;[6] these exceptions are cases in which a cancerous growth is superimposed on an existing ulcer; as the disease advances and the ulcer becomes all cancerous the hydrochloric acid is wanting in accordance with the above-mentioned fact; further, it has been shown that the total chlorine content is not diminished and that there is no increase of sodium chloride; it follows, therefore, that the stomach has secreted hydrochloric acid in normal quantities and that it has been immediately acted upon by basic bodies derived from the tumor juices; again, if a definite amount of hydrochloric acid is introduced into a clean, empty stomach it will be found that after a short time a considerable part of it has been neutralized by the alkaline juices; all this considered, we must conclude that in cancer in or about the stomach it is not a question of diminished secretion of hydrochloric acid, but rather of rapid neutralization by pathological juices. There is some loss of mobility in cancer of the stomach and this, together with the diminished amount of available hydrochloric acid, favors putrefactive processes.

The stomach contains acetic acid very early in the disease and this is thought by some to be a specific sign of cancer. I think, however, that we should exclude excessive drinking before we diagnose cancer by the presence of acetic acid, because I am under the impression that unabsorbed alcohol sometimes undergoes acetic fermentation.

In the progress of cancer there is always a progressive anemia and some observers insist on this being a specific effect of the hypothetical cancer toxin; there is a diminution in the number of red blood corpuscles and consequently some diminution in the hemoglobin content, the specific gravity being diminished—the normal Sp. G. is 1.0591 for men and 1.0562 for women; in cancer the findings may be 1.046 and 1.040 respectively, which phenomenon depends on the reduced number of red blood corpuscles.

Dr. Robert Bell has recorded variations in the electrical polarity of the blood corpuscles of cancerous patients.

The nitrogen content of the blood may be as low as 0.79 in 100, the normal being 2.0 to 2.5 per 100.[7]

Every observer knows that there are emaciation and decline of physical strength in cancer patients; with these main symptoms there occurs dryness of the skin, loss of hair, anorexia, and psychical depression. The emaciation is less marked when patients are treated with vitamines to be described below. Patients often pine away with loss of muscular power while still retaining a fair amount of fat reserve.

Von Noorden thinks that the muscular apparatus is most affected in cancer. Malnutrition is only one cause of loss of strength; the other factor is the pathological disintegration of protein mentioned above.

It was in 1889 that F. Müller carefully examined the metabolism of cancerous patients not suffering from fever or edema and found that the nitrogen loss in gastric cancer exceeded considerably the amount that could be explained as due to the existing inanition; further the abnormally increased disintegration of protein was even more conspicuous in a patient suffering from external cancer, whose intake of food was normal. In this instance it was quite impossible to balance the excretion by an increased food supply. A daily supply of 21 grams of nitrogen failed to equalize the loss which still exceeded the intake. The intake was then reduced to the verge of starvation and still the nitrogen excreted exceeded that of healthy individuals; this abnormal excretion of nitrogen cannot be demonstrated in every case.

Müller's work has been confirmed by all subsequent investigators who have worked on similar lines. There are a few cases in which a retention of nitrogen occurs, and in some cases of cancer of the esophagus a considerable increase of weight is observed. A rise of temperature may account in a few cases for the increased metabolism of protein, and Müller was careful to experiment only in cases which had no pyrexia.

It must not be overlooked that discharges from cancers are albuminous and may account for some of the waste of nitrogen in cases of gastric cancer. Washings from the empty stomach contain regularly about 0.01 gram of nitrogen which must come from the tumor, though the new growth may be too small to be accurately felt. I hold strongly and am here referring to Müller's theory of the specific toxogenous disintegration of protein in cancer.[8]

Bearing on the toxogenous theory of cancer it is interesting to recall the incidence of cancer occurring in subjects who already suffer from diabetes. Diabetes is admittedly a disease of carbohydrate metabolism and when a disease of protein metabolism is superimposed it is easy to understand how readily fatal two such conditions are likely to be.

For twenty years it has been noticed that cancerous evolution is undoubtedly influenced by preexisting diabetes. Coma is very frequent after operations on cancerous growths and the examination of the urine for sugar before a contemplated operation has an importance that is not always appreciated. In advanced diabetes where the chances of success are so limited, operations are likely to hasten the death of the patient. When any doubt exists as to the malignancy of a discharging tumor the point may be settled by the polarimeter; normal albumins are levorotary; discharges containing cancer cells are dextrorotary. Normally, the end products of the metabolism of protein are urea 96 per cent., uric acid 1.8 per cent., ammonia 1.2 per cent., and extractives 0.6 to 0.8 per cent. In cancer the figures are urea less than 80 per cent., uric acid 1 to 5 per cent., ammonia 0.2 to 13 per cent., and ex-

tractives 13 per cent. to 23 per cent. These observations were originally made by Topfor and have been confirmed by other observers.

More than forty years ago Sir Samuel Wilks, basing his remarks on 2,000 autopsies in Guy's Hospital, came to the conclusion that the edema and cachexia of cancer were due to factors accompanying cancer. If the edema and cachexia which exist so constantly in patients suffering from malignant disease are not due to cancer itself then what are they due to?

In setting out to treat cancer we must decide between the two schools of thought and act accordingly.

Are we to regard cancer as a general condition dependent on errors of metabolism, or are we to regard it as a local condition? There can be no doubt that the cachexia of cancer is a general condition, but some still maintain that the onset is purely local; with this I entirely disagree.

Some of the epitheliomata are not very malignant and cases treated by surgical operations do very well, but the most enthusiastic surgeon is bound to admit that removal of a breast does not permanently relieve or cure scirrhus. On the other hand, there is abundance of clinical evidence to prove that cancer patients treated by vitamines and hormones live longer and have less pain than those treated only by operation.

I contend that the cancer parasite does not flourish in a blood that is well supplied with vitamines and hormonies. It is with this hypothesis that I set out to describe the rational treatment of cancer.

The Vitamines and Bios.—For more than a hundred years it has been recognized that to maintain health foods must contain something more than proteins, carbohydrates, fats, salt, and water, but the nature of that something was not made known till the twentieth century was more than ten years old. Robert Bell called the substance vitols, but the name was not generally adopted; Funk introduced the name vitamines, and spent much time in trying to unravel the mystery; he thought that vitamines were complex substances with the pyramidine base. The pyramidine base is C_5H_5N. Bell thinks vitols or vitamines are metallic colloids. Vitamines will stand a temperature of 100° C. for two hours, but are quickly destroyed at 120° C.[7]

Wildiers discovered a substance which he has provisionally called Bios, and finds that it has a wonderful influence on growth. Bios is found in all cultures of growing yeast.

It is interesting to note that the laboratory work with regard to bios was being done at the University of Louvain, whose tragic fate is one of the most conspicuous blots on the good name of our time. Bios is soluble in 80 per cent. alcohol, not in absolute alcohol or ether; it is present in some extracts of meat, in commercial peptone, and in beerwort; whatever its chemical composition may be, it is not the same thing as vitamines.[8]

Starling, Bayliss, and Hopkins have pointed out that it is not enough to estimate a diet only by the caloric value of its constituents, for the presence of small quantities of substances such as vitamines, bios and hormones must be taken into account. A crystalline substance has been isolated from rice bran in the proportion of 2.5 grams from 100 kilos.[9] For medical purposes the best way is to obtain vitamines from yeast, the bottom yeast is found to be more suitable than top yeast. In many breweries the bottom yeast is washed out of the vats, and so wasted, the material therefore has the advantage of being cheap; when yeast is obtained from the brewery it is pressed to remove any beer; after going through various pressing, heating, and filtering processes, the essential constituents are precipitated by hydrous aluminum silicate, which should be in colloid form, and is known as Lloyd's reagent; the approved dose is 45 grains a day."

The custom of our time demands that some laboratory findings should be given in support of newly stated clinical experiences.

Feeding experiments were tried on a flock of twelve pigeons contained in a large cage. On feeding with an exclusive diet of polished rice the pigeons developed a form of neuritis resembling beriberi; those that were given yeast vitamines rapidly recovered; it was found that a paralyzed pigeon was able to fly again after a few doses, and was apparently cured in twelve hours.

A pigeon being experimentally fed requires 20 grams of whole grain daily to prevent beriberi, but the addition of half a gram of yeast flour will keep it in good health.

At the present time two separate vitamines have been recognized. The anti-scurvy vitamine, which is soluble in fats, and found normally in butter; and the anti-neuritis vitamine, which is soluble in water.

Eijkman, who was pathologist to a hospital in Java during 1897, noticed that fowls, when fed on boiled polished rice that had been sent down from the wards, developed a peculiar disease resembling beriberi, and so found the first explanation of the disease beriberi.

Little or nothing is known of the chemical or physical appearances of vitamines, and their presence or absence can only be detected by biological methods. It must be remembered that the vitamines reside near the husk or skin in all corn and fruits.

Turning to the uses of vitamines, it will be remembered that Captain Cook, on his second voyage of one thousand days was successful in avoiding scurvy. In 1776 he wrote: "We came to few places where either the art of man or nature did not afford some sort of refreshment or other, either of the animal or vegetable kind. It was my first care to procure what could be met with of either by every means in my power, and to oblige our people to make use thereof, both by example and authority; but the benefits arising from such refreshment soon became so obvious that I had little occasion to employ one or the other." Scurvy is a deficiency disease due to the want of vitamines and bios.

The cubs of a lioness in the zoo persistently died and a leading surgeon gave it as his opinion that their diet of cab horse was deficient in fat; this was changed for one of good class meat and the family flourished; was it only fat that was needed? I venture to suggest that it was not so much fat as vitamines, bios, and hormones that the lions required. There must be some vitamines in good

fresh meat, because scurvy was absent from the Scott and Shackleton antarctic voyages when the men were supplied with fresh meat.

Human milk is deficient in vitamines when babies are kept too long on the breast; this fact explains the incidence of rickets in some breast fed children.

In the Philippines it has been observed that the infant of a mother fed on polished rice is likely to develop beriberi, but that it is rapidly cured by a diet of fresh cow's milk or by rice vitamines.

The most important and convincing of all evidence regarding vitamines is the experience of the Japanese navy. At one time as many as a quarter of the crews were affected with beriberi, till Baron Takaki was deputed to study the diets of other navies, and he realized that the medieval custom of feeding on polished rice was the cause; the diet was changed and beriberi avoided. One more illustration will suffice. In the Strait Settlements the Chinese eat polished rice and the Tamils boil their rice whole; as a result the Chinese get beriberi and the Tamils do not. In the prisons polished rice is used and the Tamils and Chinese suffer alike. In this country nearly all the rice sold is polished to make it look white, but here it forms only a small part of our food and we get vitamines from other sources. In 1854 cholera attacked the midland counties; there were many deaths in Staffordshire and elsewhere, but the fruit growing and cider making villages of Herefordshire escaped. The physicians of that time attributed this to the custom of eating fresh fruit; it is certain that the villagers did not peel their apples and so consumed vitamines freely; it being a fact that the vitamines exist near the peel in all such fruits.

Vitamines and bios act as catalysers; the purpose of a catalyser is to set in motion or to retard the action of other substances; there are many of these in the body, without which the formation of living matter from food does not take place properly.[9]

The principal of catalysis is well understood by chemists and the following example from inorganic chemistry will serve to illustrate what happens. Hydrogen peroxide undergoes slow decomposition into oxygen and water, but if a small portion of spongy platinum be added to it, it is at once seen to decompose quickly with the evolution of bubbles of oxygen; in this experiment the spongy platinum is the catalyser.[12]

Turning from vitamines to hormones we find that there is no hormone known to have a specific action on a cancer, but it is an established fact that the thyroid gland controls metabolism, and, as we shall see, there is clinical evidence that it influences cancer growth.

The thyroid gland is known to have four principal functions.[13] (1) It governs the growth of all cells and sustains their functional activity. (2) It controls calcium metabolism. (3) It is a profound catabolic stimulent, facilitating the breaking down of exhausted cells and governing the elimination of the waste products of their disintegration. (4) It exercises a protective antitoxic and immunizing action, defending the body not only against the toxic products of its metabolism, but against invasion by disease-producing microorganisms and injury by their products.

The colloidal substance contained in the thyroid gland is understood to be its active principal and the quality of the colloid in its turn depends on its iodine content. The iodine content of butchers' meat is very low and therefore excessive or exclusive meat diet causes poverty of the thyroid (McCarrison) and degeneration of the gland.

Poverty of vitamines also causes degeneration of the thyroid. Pigeons fed on polished rice suffer from thyroid degeneration, and animals and birds in captivity seldom have normal thyroids. Bensley has found that opossums captured in a wild state when brought under domestication develop hypothyroidism, their thyroids rapidly changing from the colloid to the hyperplastic type, due presumably to an increased ingestion of protein. In an overtaxed thyroid the intervesicular tissue becomes relatively increased in amount and the vesicles empty and shrink, all of which changes are indicative of an attempt at increased activity on the part of the gland.

The thyroid gland presides over metabolism. The abnormal processes of a disordered digestion interfere with the efficient elaboration of the thyroid's secretion, thus reducing its physiological activity.

Intestinal stasis leads to subthyroidism by reason of the action on the gland of toxic products absorbed from the static bowel.[14] A vicious circle is thus established.

When we come to consider the incidence of cancer in different countries and at different periods we are struck by the fact that wherever luxurious living abounds there cancer flourishes.

Amongst the Polynesians and Melanesians cancer is almost unknown and these two races are practically vegetarians; in Egypt cancer is seldom or never found amongst the black races; in South Africa the Boers and Europeans are large meat eaters and suffer frequently from cancer, whilst the natives who are largely vegetarians seldom so suffer. In fourteen years Dr. Johnson saw only five cases of cancer in the natives and these were living as Europeans. Renner reports that during the thirty years, 1870 to 1900, there were only twenty cases of malignant disease among 22,453 patients admitted into the colonial hospital, whilst in the next ten years there were twenty-six cases out of 10,163 admissions, a slow but steady increase in cancer incidence with the advancing influence of the white men and their meat-eating habits."[15]

Many more statistics could be given but these are sufficient to show that a diet which taxes the thyroid and is low in vitamines causes an increase in cancer.

The general treatment must be preventative and curative and at both stages will include the avoidance or treatment of constipation. It has been shown that in intestinal stasis putrefactive organisms invade the small intestine and poisonous toxins are absorbed, the small intestine is intended for the aseptic absorption of food and the colon for the bacterial destruction of residues. The invasion of the small intestine by putrefactive organisms depends on the amount of pathological delay which results either from bad habit or disease and it is necessary to remember that the bad habit of neglecting the bowels is the commonest cause of the disease which sometimes ensues.

Vitamines, including bios, may be administered

as part of our food or as medicines. All fresh, uncooked fruits and vegetables are rich in vitamines and all patients in whom cancer is suspected must take as much fresh fruit and vegetables as possible when obtainable; a pound of raw tomatoes daily will supply the necessary vitamines, salads will do the same. It must be remembered that vitamines exist immediately beneath the skin of roots and just below the peel of fruits such as apples; the bloom to be so readily seen on grapes and freshly picked apples and pears is the natural yeast and contains the substance known as bios. It is plain, therefore, that an apple just picked from its parent tree does not require peeling. I am bound to admit that there is some excuse for removing the peel from an apple which is taken from a street barrow and which, as often as not has a telltale and quite unnatural polish; there is always a remote possibility of the man who polished the apple having tuberculosis. Potatoes can be scrubbed with a hand brush and then boiled, the middle of a potato is mostly starch and potato starch is not the best form of carbohydrate; raw carrot grated into soup is often a useful source of vitamine. It is unreasonable to expect the alimentary tract of a human being in our time to make living protoplasm of dead meat unless the process is aided by catalysers in the form of vitamines, bios, or both. It is not scientific or useful blindly to order everyone to become a vegetarian; what we require is a diet rich in vitamines; meat is always poor in vitamines and often free from any appreciable amount.

To avoid useless repetition I shall for the future use the word vitamines only and it must be understood to include catalyzers derived from bios also.

Like the temperance cause the vegetarian argument has suffered much from its friends. The alarming increase in the incidence of cancer synchronizes with the advance of modern meat-eating habits. It is no more reasonable to look for vitamines in Australian rabbits that have been ten years in cold storage than it was for authorities of the zoological gardens to expect a lioness to rear her family on a diet of London cab horse.

When it is thought necessary to supplement the vitamines obtained from foods, that can be usefully done by administering yeast tablets as described above; the dose is from 10 to 45 grains in the 24 hours. I generally start by ordering a five-grain tablet three times a day and increasing to two or three tablets if required. Yeast tablets given in large doses act as an aperient. Thyroid gland is useful and may be given as a routine, but care must be taken in ordering thyroid to patients likely to have old heart disease or atheroma of the arteries. The dose of thyroid is generally one grain of the dried extract, standardized to contain 0.2 of iodine; in old people it is safer to begin with half a grain. I do not think that any good is done by giving heroic doses of thyroid. Other hormones are useful in special cases. A combination of thyroid with a preparation of solar plexus often answers better than thyroid alone and many cases of uterine cancer do well on mammary and ovarian hormones. Shirlaw has recommended a combination of thyroid, adrenal, and pituitary hormones; secretin is useful in some gastric cancers. Space does not admit of my going fully into the question of hormones.

One fact that stands out above all others is that cancer patients treated with vitamines and hormones never suffer from the distressing cachoxia and general malaise that are so constant a feature in those treated by surgical operations.

Laboratory findings with regard to vitamine and hormone treatment of cancer are not so numerous as might be wished, but there is abundance of clinical evidence accumulating to prove the truth of all I have written. Local treatment alone cannot be expected to cure a general disease, but as an adjunct to vitamine and hormone treatment local measures are of the greatest use.

Case I.—Mrs. J. aged 70, came under observation January 28, 1918; when first seen she was confined to her bed, was suffering much pain and showed signs of carcinoma of the pylorus with secondary deposits in the liver. The diagnosis was confirmed by a colleague; treatment was begun with precipitated yeast vitamines, 5 grains, and dessicated thyroid gland, ½ grain, three times a day; there was improvement from the first and after two months the patient was in good general health, had no pain and could get about; when last examined the new growths were quiescent and the patient was enjoying life; she did not show any cachexia.

Case II.—Mr. C. suffered from carcinoma of the pylorus several years ago and was put on vegetarian diet by one of my colleagues. He did not go down hill and in the early part of 1918 developed a growth on the inferior maxilla for which he consulted the writer. He was put on vitamine and thyroid powders, 5 grains and two-thirds of a grain respectively; he was also given local treatment by means of the electric vibrator; when last seen the growth in his jaw was smaller and giving no trouble; in other words it was quiescent.

Case III.—Mr. B. aged 57 came under observation with a well marked epithelioma affecting the right antrum and side of the nose. Treatment with yeast vitamines 5 grains and desiccated thyroid gland two-thirds of a grain was begun January 18, and there was gradual improvement up till March 18 when it was suspended, owing to an accident; till March 25, during this period the growth enlarged very quickly and the patient was obviously losing ground. On March 25 treatment was resumed with 7½ grains of yeast vitamines rising to 15 grains, with 1 grain of desiccated thyroid. April 7 the growth was smaller and the patient was better than he had been since treatment was suspended on March 18.

These cases are cited to show that yeast vitamines as used by the writer* have a definite beneficial effect on cancer; they are not presented as a final report.

The *x*-ray treatment of cancer has not been a great success, partly because even small doses damage or destroy the lymphoid tissue in the human subject, just as Morton and Murphy found in their experiments on mice. If you destroy portions of lymphoid tissue you render your patient less resistant to any cancer cells that remain.

One other point must be remembered in connection with thermal treatments; cancer cells cannot resist a temperature of 58° C. and some are destroyed at 55° C. whilst normal epithelial cells can resist 60° C. It does not seem to me that there is a safe workable margin between 58° C. and 60° C. You cannot work at 58° C. and be perfectly sure that you will not reach 60° C. and so do too much. I venture to say that the radium treatment of cancer has not come up to expectations.

Hyperemia.—After vitamines and hormones, by

*The precipitated yeast vitamines used were specially prepared for me by Eli Lilly & Company, of Indianapolis, U. S. A.

far the most important remedy for the treatment of cancer is induced hyperemia, which is a therapeutic measure local in technique and general in its result. The importance and comparative novelty of its use justifies me in submitting some general description of the practice.

Induced hyperemia was used empirically by the ancients, but our interest in it starts about the middle of the sixteenth century, when Ambroise Paré (born 1517, died 1590) used hyperemia to cause absorption of an abnormally large callus; it is interesting to remember that Paré preceded Harvey*, and therefore could not have understood the circulation of the blood, though he may have had some notion of it.

Every organ is hyperemic during its period of functional activity and there is no process of repair known to surgery which is accompanied by anemia; on the other hand, progressive anemia is one of the most constant signs of unsuccessfully treated or untreated cancer. If we realize these facts we must surround a cancer with hyperemia, which is the most universal autocurative agent.[15]

Treatment by hyperemia aims at flooding the affected part with normal blood, for cancer is only possible where there is giving way of the natural defenses against disease, commonly spoken of as strain.

The reaction hyperemia which appears after induced anemia, such as that produced by Esmarch's bandage, is entirely independent of the nervous system.[15]

The curative effects of hyperemia are not confined entirely to the part treated. Walsh reports a case under his care at the now abandoned Tallerman Institute, which illustrated this. The patient was suffering from old intractable eczema of both hands, which seemed to have resisted all the remedies tried; heat was applied to one hand by way of an experiment, and resulted in a general curative effect on both hands.[15]

It is as well to remember that overtreatment by hyperemia is apt to cause headache and to tax the strength generally. This is due to the absorption of toxins at a rate which is in advance of the patient's ability to deal with them. I think a patient who is likely to be suffering from atheroma of his arteries should be carefully watched if under treatment by hyperemia. There is no more remarkable effect of treatment by hyperemia than the relief of pain, a most important matter where cancer is concerned.

Hyperemia produced by cupping is known to relieve the pain in pleurisy and it is said that this is due to the drawing of blood from the inflamed pleura; there does not seem to be any doubt about the relief of the pain, but I give the foregoing explanation of its mode of action with some nervousness. It may be that the relief of pain in deep seated cancer is due to the drawing of blood from the area of the disease; at any rate, I have seen a great deal of relief follow the production of superficial hyperemia in a case of deep seated cancer.

Fat is admittedly absorbed by lymphatics, but nearly all carbohydrates, proteins, salts, water and soluble albumins generally are absorbed by the capillarics; similar laws prevail with regard to absorption of pathological materials from tissues and cavities of the body. The absorption of solid or bodily elements takes place through the lymphatics.

It has been shown conclusively that active hyperemia increases absorption. Sir Astley Cooper thought the use of cupping-glass hyperemia of value in the treatment of poisoned wounds; the converse is true also, for it has been found that positively lethal doses of cocaine can be injected into a limb beneath a constricting bandage and that death does not follow if the bandage is kept tight for at least an hour.

Hyperemia has definite solvent properties. The nodules in a case of trigger finger rapidly absorb water under active hyperemia. Thomas of Cologne has cured cases of keloid by hyperemia; the solvent process has been termed autolysis and ascribed to some ferment contained in or derived from the leucocytes. No one attributes the dilatation of a stricture wholly to the mechanical action of the dilators, the active hyperemia set up in the scar softens it and makes the cure possible.[15]

Blood serum has a solvent property, as witness the maceration and solvent effect on the skin seen when a dropsical limb is punctured and some of the serum is allowed to trickle down unprotected portions of the sin. Sir Almroth Wright has shown that the liquefaction of tissue by white blood corpuscles depends for its success on the presence of abundance of blood serum. The well known improvement in stiff joints treated by massage must be ascribed to the solvent effects of the blood.

The cellular pathology of Virchow has held the field for many years, but it must be remembered that blood cells live in serum and it is only reasonable to suppose that the cells give certain properties to the serum in which they exist.

Taken all in all it seems to me that in reality the living tissues in an as yet unborn life process may achieve annihilation of intrudent poison. There is much more of therapeutic value in the blood serum than our physiology and pathology is aware of.

Coming back to our subject, hyperemia can be induced in several ways, by cupping glasses, by Esmarch's bandage, by heat, and by massage. In cancer practice much can be accomplished by means of vibratory massage, the method used by Robert Bell, in whose clinic I first saw it applied. The electric vibrator should be used for a quarter of an hour every other day or less often. There is no doubt at all that it relieves pain and hastens the recovery of the patient, but it should be used as an adjunct to internal treatment by vitamines and hormones; obviously, if you are going to increase the blood supply to the diseased area for curative purposes you must see to it that the blood is as nearly normal as possible.

Post Scriptum.

Many writers draw comparisons between tuberculosis and cancer, attributing the declining death rate from tuberculosis to the discovery of the *Bacillus tuberculosis* and subsequent introduction of tuberculin. I do not know what proportion of tuberculous patients are injected with tuberculin, but I am certain that very few recover without constitutional treatment. When first introduced tuberculin was a dangerous remedy and often did harm;

*Harvey lived from 1578 to 1657 and his celebrated essay on the circulation of the blood was publsihed in 1628.

today it is mostly used as an adjunct to general treatment.

It is interesting to consider the cancer and phthisis death rates in this country. The following figures represent the deaths from each cause per million:

Cancer.

Year	1911	1912	1913	1914	1915
Deaths.....	992	1,023	1,064	1,069	1,121

Phthisis.

Year	1911	1912	1913	1914	1915
Deaths.....	1,061	1,021	989	1,022	1,136

Diabetes.

Year	1911	1912	1913	1914	1915
Deaths.....	106	111	118	122	130

It will be seen from the above figures that the death rates from cancer and phthisis are becoming very nearly equal, and that deaths from diabetes are increasing. During the year 1915 there was in the civil population of the United Kingdom a total of 41,676 deaths from phthisis and 39,847 from cancer. I have introduced the figures relating to diabetes, because diabetes is admittedly a disease of metabolism and it helps to show that diseases due to metabolism are becoming more fatal as we increasingly sophisticate our food.

As our knowledge of chemical pathology increases I think it will be found that the predisposing cause of cancer is some break in the normal chain of complex substances which exist between protein and urea; on which side of the amino-acids the chain breaks I do not know, but the exciting cause may be some parasite, probably a protozoon..

About half the cases of cancer begin in some part of the alimentary canal; whilst we are abusing our almentary canals more and more every year, what more reasonable than the contention that cancer is a disease due to a deficiency of vitamines and their congeners and incidentally to intestinal toxemia?

42A New Cross Road.

THE POINT OF ENTRY.

By DOUGLAS H. STEWART, M.D., F.A.C.S.,
NEW YORK.

THE point of entry of germs and toxins, through which they pass from a wound into the human body may seem to be a minor point; at any rate, it is a well-neglected one. Much has been written about pus and pus organisms; yet only now, or recently, has any great attention been given to the rôle of wound contained tissue, to putrefaction pure and simple, and to the dangerous combination of the two in one host. The literature of the day contains many references to the importance of making a wound sterile; but these are rather nullified by a mention of the impossibility of so doing, unless by the employment of an antiseptic of such an irritating strength that its application will tend to accomplish rather more hurt than benefit. The advantages to be obtained through the use of some of the metalloid halogens are spread abroad, possibly a little more widely than is the result of that clinical experience that demonstrates that those substances are eczema producers and retarders of Nature's healing processes.

The use and the conservation of blood serum is being taught here and there, even though the teachers seem so lacking in economy and thrift in the matters that they value, that they allow the patient's serum to run away, to soak into the bandages, to be thrown away with the soiled dressings while some attempt to replace it or its functions is made through the generous application of horses' serum. Excision or debridement is practised, all pieces of torn or contused tissue are removed lest they harbor and nourish invading germs and this is well; when possible and when even microscopic-sized fragments of dead or dying tissue are carefully taken away before they putrefy. But were the many expedients of the day admittedly feasible, successful, and practicable, perhaps nothing more need be said. The bacteria would soon be destroyed or rendered harmless and their evil works would cease. Though as things are and in view of the partial success that attends immense efforts to kill bacteria, perhaps it may be well to bestow a little of our care upon the party attacked and especially upon the point of entry rather than to give our whole attention to bactericidal measures.

In the great industries there is or was a set of men who employed putrefaction for a useful purpose. Such men were known as tanners and they placed the hides of animals in underground vaults. There those hides were allowed to putrefy or sweat until the hair and the scarf skin became so softened that their removal was an easy process; but with that removal the points of entry for that hide were opened. Therefore had the arrest of the process not been under control the whole of the subjected hide would have been rotted or rendered valueless. By submerging such a hide in a strong solution of tannic acid the microbes, the yeasts, and the proteins were all precipitated or fixed and the tissue of the hide was infiltrated or rendered hard, tough, and putrefaction-proof. In other words, the portal of entry was blocked by a coagulation of albuminoids upon the surface, be-

neath the surface and within the meshes of such a hide.

A simple experimental example lies in suspending two pieces of meat in separate test tubes, one of which contains a 10 per cent. solution of tannic acid and the other contains plain water. Both test tubes are to be kept at a temperature of 80° for four or five days. Or, in another trial, two pieces of catgut, one plain and the other tanned, may be placed in an infected wound, though they themselves should be sterile. After a few days (5 to 7) the contrast will prove very great when the two are submitted to careful examination. In a large tannery that the writer was once familiar with certain sorts of leather were changed from vat to vat for a year or more, yet they did not putrefy, although as has been said the process of putrefaction was under full headway when the hides were first introduced into the tanning mixture, which latter the tanners tasted without apparent harm.

In the MEDICAL RECORD of March 28, 1896, there appeared an article by Veeder in which it was stated that a certain patient who had had large suppuration sinuses had had pretty much all sorts of antiseptic treatment; but after those tracts had been carefully injected with solutions of tannic acid, the pus was squeezed out like cheesy worms and prompt improvement followed. This would be a sort of vice versa for the matter under present discussion, for in that instance the process might be termed a blocking of points of exit. However, the point remains to-day as it was then, *i.e.* the solution should be of sufficient strength and should be so applied as to make a visible change in the pus—if pus is present, of course.

As for serum and wound repair it seems as though many men had the idea that serum should be tapped and run off lest it produce tension. Though it surely means something when so many surgeons who are actively engaged send back word that wounds are to be closed in the shortest possible time. It also has a meaning that upon all sides is heard a condemnation of wet wounds or even so much as a wet spot upon the edge or margin of a wound. Such things surely mean that serum, leucocytes, etc., are precious and should be treasured and retained in the proper environment. It is also implied that dryness and putrefaction are contradictory conditions and that a profuse flow of wound discharges is a waste of natural efficiency. Therefore it behooves us to get a wound cleaned, dry, and closed rather than to wait until the whole state of affairs becomes irremediable through a combination of moisture, putrefaction, and processes akin to peptonization.

The presence of the first member of the combination is perhaps the most neglected factor in the modern treatment of wounds, for it makes possible all of the other factors. It must be evident to every student of the matter that the best possible condition for rapid healing is one where a wall (as it were) of tanned albumin prevents either tension or invasion; while the blood vessels are not contracted nor are serum and antibodies prevented from traveling up to the very plugs of tanned proteins that block the outlets and terminals. Tissues are hardened, are infiltrated, and their openings are sealed. All of which processes the microscopic examination will make comprehensible, and some understanding may result from a strong application of tannin solution to one's tongue or cheek-membrane. Tannic acid is an antiseptic even in the strengths of a grain to the ounce; but the present paper deals with it as a preservative astringent. A defender because it is a drier. A statement that holds good for the treatment of wet ulcer, a weeping eczema, a hyperidrosis, a ruptured blister, or any similar condition of discharge. Tannic acid acts equally well in a nosebleed or on an open carbuncle. The preparation employed is the U. S. P. tannic acid test solution. A hypodermic with a rather large caliber needle, the point of which has been carefully blunted, is an excellent instrument, and the time spent in allowing the medicament to soak in, to come in contact with every particle of that wound, to obtain the change of tissue color and to dry is never wasted.

The solution referred to in the preceding paragraph is usually labeled No. 119, because that is its proper number among the standard test solutions. An apothecary would know it either by name or number. Needless to say, its use is not accompanied by pain; but if one wishes to close a new wound at once upon its receipt, then this solution is a capital one to apply to such a wound immediately before stitching. It has a place either when employed alone or with other measures.

The writer has an idea that all wounds should not be treated alike, and the limitations of this solution have not yet appeared. He only knows that over three hundred wounds that were doing but poorly under other modes of treatment at once began to do well and progress to recovery when put upon this method. This solution is both easy to obtain and easy to apply. It certainly has a place and perhaps a wide one. Though wet in itself it soon drys and is therefore applicable to any system of dry dressing. However, the fact emphasized here is not its power as a germicide; that is well known to be great; but its ability to close the point of entry against the invasion of microorganisms.

The dressing powder with which the writer is most familiar is ethylene-diamine-sulphate of mercury one grain, sodium perborate one scruple, and boric acid to make an ounce. The wound to be treated is tanned and then this is put upon it, abundantly. Sometimes a doctor or a nurse puts the powder upon the wound first and follows that with Solution No. 119, U. S. P. If this is done the wound cannot be tanned, for the tanning solution goes into a globular or spheroidal state and runs away from the wound, or from any other predetermined locality after the manner of quicksilver when put upon a platter. Let the technique be as described in the body of this article and there will be neither difficulty nor disappointment, for these are both sequential to a deviation from plain directions.

128 WEST EIGHTY-SIXTH STREET.

CONGENITAL LARYNGEAL STRIDOR.

REPORT OF TWO CASES WITH CLASSIFICATION OF LARYNGEAL AFFECTIONS.

By JULIUS LEVY, M.D.

NEWARK, N. J.

PEDIATRICIAN, NEWARK BETH ISRAEL HOSPITAL.

Two cases of this condition have recently come to my notice. The first case of congenital laryngeal stridor was seen in a child of five months, the second, in a child of eight months. Both cases had previously been seen by a number of physicians and many diagnoses had been made, among them asthma, acute bronchitis, laryngismus stridulus, and acute laryngitis. Since the histories of the two cases and their course were practically identical it will be sufficient to describe the first case.

The stridor in breathing was noticed two days after birth, was confined entirely to inspiration, and while it became intense during crying, was always present. The inspiratory stridor could be heard across the room, while the expiration was quiet and unobstructed. In spite of this obvious difficulty in breathing, which was attended by retraction of the supraclavicular spaces and strong downward and inward traction on the lower ribs with bulging of the abdomen, there was no cyanosis, no hoarseness, no cough. The baby was breast-fed, somewhat pale, but showed no evidences of rickets or any other diseased condition. In coming to a diagnosis we were able to eliminate catarrhal affections of the larynx, like acute laryngitis, by the absence of hoarseness and cough, membranous affections by the absence of all difficulty in expiration, spasmodic affections, like laryngismus stridulus, with which it is most often confused, by the continuous character of the difficulty.

The diagnosis of congenital laryngeal stridor is made then when a child under one year of age presents marked difficulty in inspiration only, which dates from birth and is not accompanied by cyanosis, hoarseness, or cough.

The pathology of this condition as given by Ley of England in 1837, and verified by Koplik, is a congenital maldevelopment of the epiglottic and eryepiglottic folds. At about one year, through the general growth and development of the larynx, these folds no longer interfere with normal inspiration and a spontaneous recovery takes place. No treatment is indicated or possible and the prognosis is invariably good, as the child is entirely well by the end of the first year.

From the fact that no reference is made to this condition by Rotch in his book, "Diseases of Children," published in 1897, or by Kerley in 1914, it would appear that this condition is not as frequently recognized or as well known as one would expect it to be from the fact that it was fully described by Condie of Philadelphia as early as 1850. Furthermore, the more literature I consulted the more confused I became in regard to the various affections of the larynx in infants as there was very little agreement among the different authors even in the definition of terms. Thiemich of Breslau says that that which is often called laryngismus stridulus is laryngospasm and that this latter term should be used in all cases of audible breathing in infants, including congenital laryngeal stridor. From this it would appear then that he considers congenital laryngeal stridor to be due to a spasm of the larynx. Koplik, in describing congenital laryngeal stridor, states it is often associated with rickets, to which it obviously can bear no relation since it is a congenital condition and due to maldevelopment. It would appear that here he was thinking of laryngismus stridulus, as in discussing this latter condition he quotes Henoch and Kossowitz for the statement that it is present at birth.

Much confusion was also found in the discussions on etiology and pathology.

The thymus gland has figured in the etiology of laryngeal affections at least since 1712 and every decade since then some one has rediscovered the thymus as the cause of laryngeal stridor, even though it was clearly shown by Condie in 1850 and Jacobi and others in 1859 that the enlarged thymus was not associated with this condition and anatomically could not produce any irritation of the recurrent laryngeal nerve which is given off from the vagus at a point where the thymus cannot produce any pressure. But medical theories die hard, for in 1914 Kerley again speaks of the thymus gland as a frequent cause of laryngismus stridulus.

Authoritative text books show that there is still a great deal of confusion between laryngismus stridulus and congenital laryngeal stridor, and particularly in the description of laryngismus stridulus is there considerable contradiction among the older and more recent authors. This is considered a spasm of the larynx by most physicians to-day and is so described in most of the text books, but in 1850 Condie referred to the statement of Ley of England that laryngismus stridulus is not due to a laryngospasm but to an impaired innervation which prevents the proper opening of the glottis, and in 1859 Jacobi stated in his classical description of this condition that few have a correct conception of the physiological explanation of the symptoms of laryngismus stridulus which, according to his view, are not adequately explained by the spasm of the larynx. He divides the attack into three stages: the first stage is characterized by a sudden and entire apnea, respiration stopping suddenly and entirely for a few seconds, the face is bloodless and the entire muscular system is in a state of paralysis; the second stage is characterized by a return of the muscular action of the larynx as a result of stimulation by the recurrent laryngeal nerve and the spinal nerves of respiration, which causes a violent crowing inspiration; the third stage consists of convulsive respiratory action, sometimes accompanied by general convulsions or carpopedal spasms. This description of the first two stages coincides with the "holding breath spells" of Meigs, which, however, Thiemich claims is an hysterical expression of a neuropathic constitution and that it has nothing in common with laryngospasm.

The best definition of laryngismus stridulus would appear to be that it is an expression of an

abnormal excitomotor nervous system, is usually met with in children six months to three years of age affected by rickets, and is characterized by apnea followed by spasm of the larynx.

The word "croup" in the description of laryngeal affections also causes much confusion. The older authors frequently include in this term membranous laryngitis, laryngismus stridulus, and larngitis stridulosa and though later writers clearly define these conditions at the beginning of the chapter, the description of the onset, symptoms, and prognosis leave much to be desired in clearness and definiteness. Much of the confusion in the description of laryngeal affections is apparently due to the persistence of erroneous conceptions of pathology or etiology, as when laryngismus stridulus is called thymic asthma by some or the thymus gland is given a prominent place in its etiology.

After consulting text books and literature I attempted to elaborate a classification of diseases of the larynx in infants that would clearly distinguish the various conditions on an etiological basis and permit one to have a definite conception of the pathology, etiology, and prognosis of each condition described. It has simplified the subject for me and may be found useful by others.

Classification	*Pathology.*	*Etiology*
I—Congenital Laryngeal Stridor	Maldevelopment.	Heredity and prenatal factors, syphilis?
II—Laryngitis.	Inflammation.	
A. Simple.		
1. Acute.		
a. With spasm.		Extension of catarrh of nasopharynx.
b. Without spasm.		Vasomotor disturbances.
2. Chronic or Subacute.		Irritants, adenoids. Tumors } of Tuberculosis } Glottis Syphilis }
B. Membranous (diphtheria).		Klebs-Loeffler bacillus.
III—Neurosis.		
A. Laryngismus Stridulus.	Neuropathy	Neuropathic inheritance. Malnutrition. Rickets.
B. Laryngospasm.	Nerve irritation.	Pressure or stimulation of recurrent laryngeal nerve from tumors, enlarged thyroid, enlarged glands. Cerebral conditions like hydrocephalus. Spasmophilia.

191 Littleton Avenue.

DRUG ADDICTION AND THE MEDICAL PRACTITIONER.

By Thomas W. Edgar, M.D.

New York.

What am I to do with my drug addiction cases? This is the question that confronts the general practitioner frequently. Thanks to the legislative body in our State, we the practising physicians, hestitate when one of these unfortunates enters our consulting room and we either refer the patient or boldly state that we are unable to administer to his wants in precious grains.

Legislation has, through the creation of certain laws, practically made it impossible for the busy general practitioner to appreciate and understand just where his place is in the treatment of this serious illness. Laws and their amendments have inculcated in the minds of the physicians that it is hazardous to give aid to drug addicts, inasmuch as, if narcotics are prescribed, it will lay open the giver to investigation, prosecution, and frequent visits from the authorities.

The situation to-day regarding drug addiction is in an upheaval; not one physician in ten wants to treat an addict, because he feels that the procedure is too hazardous. The consequence is that he refers the patient (if he has the money) to an institution, and if the addict is without funds he is turned away, finally reaching and hitching up with the charlatan, who is only too willing to cater to his or her needs.

What is the result? Institutions are flourishing, charlatans are getting rich, and drug addiction is increasing.

The drug addict must be looked upon as one suffering from an illness, as an individual afflicted with chronic intoxication. We, the physicians, must appreciate that these unfortunates are not degenerates in the true sense of the word, but mortals laboring under adverse conditions, bowed down with the toxemia of their addiction. It is just as unfair to place the stigma of degeneracy upon them as it is to apply the same term to the users of tobacco; both are habits and both are injurious.

It is high time that the medical fraternity, especially the physicians of this great city, wake up to the fact that narcotism is becoming a menace to society, and that unless it is taken in hand and checked by personal cooperation between physician and addict, the State will assume measures to place this class of sufferers in the criminal category and again our jails and prisons will revert to the old régime.

The simple fact that drug addiction has not decreased since legislation has played its part is one of the strongest arguments in favor of every physician giving this question his timely thought. Learn the fundamental elements of treatment, consider addiction as a disease; and then treat this illness personally in your own office or the patient's home. You can do much and accomplish more in reclaiming the addict than all the institutions put together.

The law allows a licensed physician to dispense narcotics by prescription, if he is registered under the State Department of Health and the Internal Revenue Department in conservative dosage that is conducive to the health and needs of his patient. Nevertheless there are certain wolves in the profession who use this as a cloak, in order that they may seemingly traffic in narcotics and fill their pockets by bleeding the unfortunate addict.

Would it not be advantageous for each conscientious physician to treat his addiction cases personally; gain some knowledge of their affliction, and keep them from the hands of the unethical vender of drugs, whose slogan is profit?

The following suggestions may be of help to the general practitioner, and if carried out may meet with success in some cases.

The treatment of narcotism in my mind is based on five cardinal principles, namely: (1) Estimation of daily dose (24 hours); (2) eliminative treatment; (3) body weight; (4) sanitary and hygienic requirements; (5) medication and mental therapeutics.

Previous to going somewhat into detail, regarding the above I might say there is not a "specific" known for the cure of drug addiction, and for that reason medication is useful only as the necessity arises and the symptomatology requires.

In each case of drug addiction it is advised that a complete history be taken and a thorough physical examination be made, going into detail regarding cause of addiction, method of introduction, etc., noting the weight, degree of reaction, and whether or not the addict is a mixed case, taking along with the narcotic alcohol, tobacco, etc.

Estimation of the daily quantity of the drug taken is of importance, inasmuch as it gives the physician a definite idea as to the amount of the drug necessary to sustain the individual, and carry him through the day; secondly, it is the amount that enables the patient to establish his mental equilibrium, and combat his inherent longings and cravings; in other words, the addict's point of relative tolerance is indicated by the amount of drug taken in a given length of time. Less will shatter his equilibrium, more tends to act as excess luggage, producing a degree of toxicity in proportion to the amount indulged in.

It is an established fact that morphine is excreted mainly by the digestive tract, and is found in large quantities in the feces. This is more so in the recent addict than in those who have been addicted for a longer period of time. The explanation of this being that the old addict has formed a tolerance for the drug and his tissues are better able to oxidize, leaving less of the drug to pass into the intestine.

Thus purgation is a very popular form of treatment, great stress being laid on its beneficial results, while the suffering it causes is never mentioned except by those who have undergone the blue mass and calomel diet. The principle is correct, but the methods used are harsh and not conducive to body comfort.

I have found that the most satisfactory method of elimination is by the use of high colonic irrigations, made of hypertonic salt solution (NaCl), the patient taking one of these night and morning. The lower bowel and colon are thoroughly washed; the residue of fluid remaining in the intestine, which is of greater concentration than that in the intestinal wall, calls forth by osmosis more fluid, thus depleting the body in the surrounding area, with a consequent diminution of drug absorption in the intestinal canal. In this way the same eliminative results are obtained without the suffering, griping, and diarrhea which weaken the patient.

Body weight is to be charted on each visit to the office, as it is a most valuable metabolic indicator. Morphine tends to produce anorexia, with a loss of weight. This must be overcome by an increased diet of those food stuffs which will supply the loss, namely, the sugars and proteins. It is often advisable to supply artificially pepsin and diluted hydrochloric acid, as often the secretion of the stomach glands is greatly diminished, due to the action of morphine. Feed the patient up to the limit of his appetite with good wholesome food, being careful to select those food stuffs that are easily assimilable.

The sanitary and hygienic requirements of the patient are not to be neglected, as is so often the case. A hot bath is to be taken nightly, after which the skin of the entire body is to be rubbed with a heavy Turkish towel. This opens up the pores and helps elimination. Another bath worthy of note is the rock-salt bath. Have the patient buy some cheap ice-cream maker's rock salt; sew it in a bag, about a pound or so, and introduce it into the bath, three times weekly. This is a good skin stimulant.

The teeth should be thoroughly cleansed after eating. Sleeping, fresh air, regular evacuation of the bowels, habits such as staying up late at night, and associating with other addicts should all be looked into. Guard the hygiene of the patient; it will help him attain the goal of his desire.

Medication. As I said previously, a specific for drug addiction has not yet been found; consequently we must confine our medication to those symptoms displayed by our patient that need to be alleviated.

After determining the amount of drug taken daily, it is wise to prescribe enough to last for this length of time. I always feel that I get better cooperation from the patient if I give him only enough drug to last him for twenty-four hours. This method keeps him coming to the physician and the latter becomes of more importance in his life than he would otherwise, aside from giving the physician a good opportunity to study his condition daily. Secondly, he becomes dependent on his physician for his daily supply, and in this way is kept from going to an outsider for his dose.

If the patient is an addict of six months or a year standing it is advisable that the dosage be divided into three or more parts and administered on a full stomach; this prevents absorption to some extent. If divided doses are not practicable have the addict introduce some food into the stomach at the time of taking his dose.

Along with each dose of the drug one-fifth grain of calomel is given for its stimulating action on the gall-bladder. Its use often prevents constipation.

Start the patient on this treatment immediately; see him frequently, never lay stress on the fact that a cure is to be effected shortly. Establish in his mind that ultimately he will automatically cease to labor under his present illness and that by cooperation and intimacy with the physician and through the latter's appreciation of his or her condition the toxemia will gradually be lessened and the body reach such a state of resistance that artificial support will not be necessary. Always be candid with the addict; never allow him to cast suspicion on your arguments; always dominate the situation while in his presence.

After gaining your patient's confidence and establishing in his mind the fact that you are not going to rob him of his precious drug, begin to decrease the daily dosage by small quantities, de-

pending on the reaction of the patient. Never disorganize the mental equilibrium and have the addict complain that he is not getting enough. Slowly you will find the tolerance decreasing. When the second decrease in dosage is made prescribe strychnine sulphate in thirtieth-grain doses morning and afternoon; this tends to stimulate peristalsis and will act as a general tonic. Continue decreasing the dosage constantly, always taking the addict into your confidence.

This simple treatment will produce results in most cases of mild addiction in from four to five months.

The auxiliary treatments by mental suggestion and mild state of hypnosis are to be recognized by those capable of their application, and are factors worthy in all addictions.

Personality, sincerity, and sympathy with an appreciation of the clinical picture of your patient, are assets necessary in the successful application of treatment.

766 West End Avenue.

A SIMPLE THERAPEUTIC TEST OF THYROID FUNCTION.

By HENRY R. HARROWER, M.D., F.R.S.M.,

Los Angeles, Cal.

There are two broad classes of disordered thyroid function: those in which there is a secretory disturbance—the numerous cases of hypo- and hyperthyroidism—and those in which there are structural changes in the thyroid gland—the various forms of goiter.

The diagnosis of goiter is not as easy as some have thought, for while the struma may be most obvious, and this "diagnosis" may be made by the patient, or by any one with eyes to see, there are several forms of goiter, and a real diagnosis should include differentiation of the kind of struma that is present, and particularly the establishment of definite knowledge as to the functional status of the enlarged gland.

Obviously, there is great need of knowing whether a given individual is suffering with a simple hypertrophy, or whether this hypertrophy is accompanied by hypersecretion. In the one case the treatment may include the administration of thyroid extract, and perhaps iodine, while in the other such measures promptly aggravate the condition. Many large goiters are not associated with increased thyroid secretion, and, on the other hand, many cases of thyroidism show no evidence of local glandular enlargement.

It is an advantage to establish an appropriate measure of thyroid functioning in many cases where these two divergent states are suspected, and this is not difficult when the therapeutic test is applied.

It is well known that some patients are very susceptible to thyroid feeding, and small doses cause much discomfort from heart hurry and increased nervousness. Certainly such cases should not receive this kind of treatment, and before it is instituted I have followed a routine which is so simple that I have hesitated to publish it. Nevertheless, it is so effective, and of such decided utility in the differential diagnosis of this particular factor in various thyroid disorders, that I am outlining it here, and expect to hear that many have been doing something of a similar nature.

Just as we are satisfied to have approximate knowledge of the elimination of urinary solids by taking the specific gravity of the 24-hour urine and figuring the "total solids," or are benefited in our work by the very inaccurate but approximate Tallquist hemoglobin test, so we can be satisfied with something approximate if not absolutely accurate. As a matter of fact, absolute accuracy is rare in clinical laboratory procedures, and with the possible exception of the Kjeldahl urinary nitrogen test, and perhaps some of the more recent tests in blood chemistry, all our diagnostic figures are merely approximations. If, however, there is a more or less uniform factor of error, which is found each time we make a given test, the diagnostic value of our work is just as great, and we ignore the lack of accuracy and profit materially by this kind of knowledge.

The functional test for thyroid secretory activity is not scientifically accurate, and, so far as I know, it is not possible to establish a norm of this character and then to be able to say that Mr. X is suffering from a 40 per cent. hypothyroidism, or that Mrs. Y has a hyperthyroidism 70 per cent. above the average. We are glad to know that in this last hypothetical person the thyroid balance is extremely sensitive, and is overthrown with a certain measurable influence.

The Loewi test of sensitiveness to adrenalin instillations is of a similar nature, and while its accuracy has been frequently impugned, nevertheless it is indeed a helpful procedure in suitable cases. So is the following:

The individual whose thyroid secretory function it is desired to measure is given a series of graduated doses of standardized thyroid gland, at uniform intervals, for a certain period of time. During this time the patient makes careful and uniform record (a small chart facilitates this, and when it is used the findings are much more easily seen) of the pulse rate, and adds in a few words any other influence noted, and which the physician looks for with a stimulated thyroid function.

I have used varying doses of thyroid and have given them over differing periods. At present I use and recommend four daily doses of one-half grain, one grain, and two grains of U. S. P. desiccated thyroids respectively. Ordinarily, three days suffices for the test, though it may be advisable to continue the pulse record for one or two days before and two or three days after discontinuing the capsules. Here follow the written instructions which I hand to the patient:

> Take one small capsule at 8, 10, 12 and 2 o'clock. Make a note of the pulse rate, after resting at least ten minutes, at 9, 12, 3, 6 and 9 P.M. On the second day repeat this procedure, using the medium-size capsules, and on the third day use the large capsules in the same way. Do not eat or drink within half an hour of counting the pulse. It is best to arrange to eat after counting, as a full stomach sometimes modifies the rate. Always maintain the same position, preferably sitting, when counting. It is essential that hurry and exercise immediately before counting be studiously avoided. Keep a record of the pulse variations for a day and a half after the capsules are taken, or for five days in all. Carefully enter the findings on the chart. Note any other manifestations which you think may be

connected with taking the capsules on the back of the chart.

Ordinarily, this routine causes no appreciable influence upon a normal individual, while patients whose production of thyroid hormones is sufficiently increased show considerable increases on the third, and perhaps the fourth, day. In obviously hyperthyroid individuals the procedure is unnecessary, and should the test be applied in a case where the thyroid susceptibility is high—*e. g.* where the thyroid secretion is materially enhanced by this feeding—it is best to omit the large capsules altogether. Sometimes even the first series of doses is enough to start the pendulum swinging violently, in which case no further capsules need be taken, though it is well to keep track of the pulse rate for several days.

Conclusions.—It is advantageous to have an approximate knowledge of the thyroid secretory activity, especially in goiter, where it is planned to institute thyroid therapy. This can be measured quite satisfactorily by graduated thyroid feeding and carefully recording the pulse.

Where this simple procedure is carried out indications for or against thyroid feeding are established with comparative ease.

711 Baker-Detwiler Building.

Medicolegal Notes.

Insufficiency of Evidence of Negligence—Failure to Move Patient to Hospital.—Action was brought in tort for the alleged negligence of the defendant physician in the care of the plaintiff, an infant, by reason of which he became blind. The defendant signed a birth certificate which stated that he personally attended the birth of the plaintiff, although he admitted he did not deliver the child, but attended him between five and six hours after he was born. He testified that when he was first called he put a solution of nitrate of silver in the plaintiff's eyes; this was denied by the plaintiff, who offered evidence to the contrary. That such treatment was proper, "and is a part of the technique of childbirth," was admitted by the defendant and others; and there was also evidence that the administration of the solution of nitrate of silver at birth "would make the likelihood of the development of the disease of ophthalmia, which caused the blindness, very much less. "The defendant offered evidence that even if no solution of nitrate of silver was administered at birth, it was shown that the disease was due to a secondary infection, as the symptoms did not develop until eight days afterwards, and that the failure to give the treatment made no difference. The questions whether the defendant failed to administer the treatment or not, and if not administered whether the plaintiff's blindness was due to such omission as a proximate cause, were held rightly submitted to the jury, which returned a verdict for the defendant. There was nothing to show that the plaintiff's eyes were affected with ophthalmia until April 22, 1918, when the right eye became swollen and red and had an unnatural discharge; the left eye was not so badly affected. There was evidence that the defendant was called on April 24, 1916, and after being solicited to come on several occasions, appeared at the house of the plaintiff's father on April 25, 1916, between 5 and 6 o'clock in the afternoon; that at that time the plaintiff's eyes were swollen, red and closed, with pus coming from each eye when opened, and the defendant administered treatment; that the next afternoon between 5 and 6 o'clock the defendant came again and took a smear from the plaintiff's eyes, which were in a worse condition than on the day before. The records of the health department of the city of Boston showed that written notice of the case, bearing a postmark "12.30 a. m., April 27, 1916," was received. The case came before the Massachusetts Supreme Court upon the plaintiff's exceptions to the exclusion of testimony and rulings and refusal to give rulings by the trial court. It was held error to grant requests for rulings that if the infection in the eyes came from an outside source in no way related to treatment by the defendant, the jury should return a verdict for him, and that, if the jury found that the defendant did not have charge of the birth of the child, he owed no duty to it to put drops of nitrate of silver in its eyes, and the jury should return a verdict for him. The evidence was held not to sustain a finding that the defendant's failure to attend the child promptly was negligence. While it might be that the plaintiff would have received better medical treatment if he had been removed to a hospital, yet the defendant's failure to order such removal did not of itself constitute evidence of negligence sufficient to justify a verdict for the plaintiff. While a physician may advise the removal of a patient to a hospital, in an ordinary case he has no authority to order such removal. The testimony relating to the plaintiff's home and whether treatment there would have been proper or would have been more efficient and desirable in a hospital, was held properly excluded. It was also held that if the defendant violated the State statute by failing immediately to report the case to the board of health after he knew that the child's eyes had become inflamed, swollen and red, etc., the failure was evidence of negligence on his part. Whether he immediately gave such notice was held to be a question for the jury.—Medlin v. Bloom (Mass.), 119 N. E. 773.

License to Practise Medicine.—The Illinois Appellate Division holds that the State Board of Health has the right to sue for and recover the penalty provided in the Illinois statute relating to persons practising medicine or treating human ailments without a certificate issued by that board, and providing that such persons shall forfeit and pay to the People of the State of Illinois for the use of that board certain sums to be recovered in an action of debt. One who advertises, professes, offers, undertakes, or pretends to undertake to diagnose, treat, heal, or benefit a patient, regardless of whether that patient is or is not suffering from any actual ailment or disease, and who charges or accepts compensation therefor, is practising medicine within the meaning of the act. Evidence was held sufficient to show that the defendant was practising medicine within the meaning of section 2 of the act, providing that it shall be unlawful for any person to practise medicine in any of its branches without a license so to do from the State Board of Health, and section 9, providing that any person shall be registered as practising medicine within the meaning of the statute who shall treat or profess to treat, operate on or prescribe for any physical ailment or any physical injury or deformity of another, where the defendant undertook or pretended to diagnose, treat and cure the trouble of his patients by a general formula of diagnosis that "the bones or vertebræ of your back are out of their normal or proper position, etc.," and advertised and assumed or pretended to be able to "place those bones of the back in their normal or proper position," the result of so doing to be health, such adjustment being or being pretended to be by applying pressure and applying pressure and manipulation with his hands.—People v. Kane, 205 Ill. App. 32.

Statements to Physician as Evidence.—A physician, called as a witness by his patient, suing for a personal injury, may testify as to the present symptoms of his patient, and repeat the statement of the patient to him as to such symptoms, but may not repeat the history of the case given by the patient during the examination made by him. In the case in question the physician first examined the plaintiff for the purpose of treating her about 11 months after the injury. The only testimony given by him as the plaintiff's witness which could be said to be violative of the rule stated above was given in answer to the following question, viz.: "At that time she gave you the statement about her complaint?" This question was objected to by the defendant's counsel on the ground of hearsay, and the trial court overruled the objection. On appeal it was held that this ruling was entirely proper, for under the rule adverted to above the question was unobjectionable in form.—McMahon v. United Rys. Co. (Mo.), 203 S. W. 500.

Military Medicine.

The Oto-Rhino-Laryngological Service in Italy.—Major W. Sohier Bryant, M.R.C., U. S. A., writes in the *Journal of Laryngology, Rhinology and Otology*, April, 1918, praising in the highest terms the organization and efficiency of the Italian military oto-rhino-laryngological service in Italy. He found that the Italian army had advanced further in medical specialization than the other allies. Their various specialists are organized in close association. The oto-rhino-laryngological specialty is enormously important in this war, because of the great number of defective ears. The importance is observed chiefly from the medicolegal point of view because there are so many cases of defective ears antedating military service, so many are caused or aggravated in the service, and so many are caused by the autolesionists. In fact, the otological specialty may be said to be of as much importance as all the other specialties put together because of the great medicolegal importance of the ear. Bryant found oto-rhino-laryngology no less important in Italy than in France. In Italy there are more autolesionists. After eliminating the cases of trachoma from the ophthalmological total, the number of ophthalmological patients in Italy is not greater than the oto-rhinolaryngological cases. In Italy, trachoma forms half the ophthalmological service. There are many more wounds of eye than of ear.

Bryant considers that the comparative importance and excellence of the Italian medical service challenges admiration and he wishes that every one interested in the service and administration of military medicine could visit Italy to study the Italian organization and efficiency. He cannot express in too strong language his appreciation of the patriotism, scientific spirit, cordiality and hospitality with which the medical department received him everywhere. Kindly interest and courtesy were never lacking on the part of the Italians during his tour.

Maintaining the Health of the British Army.—Col. George G. Nasmith read before the American Public Health Association at Washington, D. C., a paper entitled, "How the Health of the British Army is Maintained" (*American Journal of Public Health*, April, 1918), in which he said that it was necessary to realize that in the temperate climates of Europe the vast majority of communicable diseases of importance from the military standpoint were contracted largely from three sources. (1) Directly from throat and nose secretions; this includes practically all of the ordinary diseases, like measles, whooping-cough, influenza, colds, pneumonia, scarlet fever, diphtheria, etc. (2) Directly from biting insects: *e.g.* malaria, typhus fever, plague, etc. (3) Indirectly through intestinal secretions, containing the germs of typhus fever, cholera, dysentery, etc., gaining access to the body through contaminated water, food, and flies. With this outline in mind it was easy to see that it was possible for such diseases to be held in check, provided that the sanitary and medical organization was such that the germs from one infected soldier could be prevented from reaching another. It was obviously essential in the first first place to remove from the army, at the earliest possible moment, every case of communicable disease after it had been diagnosed. This meant that there must be some means for picking out soldiers who showed symptoms of disease, which really came down to the fact that medical officers must always be on the alert and carry out the instructions of the medical services of the army with dispatch. In the British Army this was one of the very important features in the control of epidemics. If a man was suspected of having any communicable disease he was instantly placed under quarantine until the diagnosis had been confirmed, after which he was removed from the army altogether as a possible focus of infection. This method was practically the only means of eliminating diseases such as measles and scarlet fever, which could not be diagnosed by bacterial methods; but, of course, the procedure was employed in all other kinds of communicable diseases. Great Britain had been fortunate above all other nations in this respect, that she sent over, at first, a small army of regular troops, perfectly equipped from the medical standpoint, as well as in every other way. Efforts had been made for years to remove typhus "carriers" from the regular army and naturally no soldier was sent into the field who was known to have or to be a "carrier" of any contagious disease. Furthermore, the soldiers had practically all been vaccinated against smallpox and inoculated against typhoid fever. As division after division was sent out to the army in France, they too were completely equipped with sanitary squads, casualty cleaning stations, field ambulances, water carts, and other necessary medical equipment. Consequently, as the army grew and expanded into a huge force it was thoroughly equipped not only with the necessary apparatus for caring for the sick and wounded, but also with the experience acquired by those already in the field. In this way the British Army differed from all our European allies, which had been compelled to mobilize everything at once and found themselves woefully lacking in medical equipment and personnel. It could be readily seen that the British Army began under auspicious circumstances, and that thereafter its freedom from communicable diseases depended to a great extent on the preventive measures adopted. All excreta behind the front line and reserve trenches was destroyed in numerous incinerators which were kept burning night and day. The British Army was the only army which had succeeded in doing this. All other excreta which could not be burned was buried so that it could not be reached by flies.

It was the rule to sterilize all water used for drinking purposes, either by boiling, by bisulphate of soda, or by chlorine. The method of chlorinating water on a small scale in general use in the army, as it is in all of the other allied armies, was brought to the attention of the British Army authorities by the publication of a method evolved by Nasmith in 1909. This was particularly useful in the trenches where it was possible to sterilize perfectly a pail or a barrel of water if necessary. Small tablets of hypochlorite of lime, each one sufficient to sterilize a pail of water, were also ordered and issued to the first Canadian division

and proved useful. The great bulk of the water supply, however, was sterilized directly in the water carts by adding one or two spoonfuls of the dry chloride of lime to the partly filled water cart, the mixing being done by the addition of the rest of the water and by the agitation during the trip back to the place where the cart was stationed. In addition to this, large mobile filter units after a plan draughted in 1914 and officially suggested by Nasmith in 1915 after experience in the field, were adopted throughout all the British armies. These mobile filters are capable of filtering and sterilizing large quantities of water and delivering it to water carts or into standpipes, ready to drink. A check was kept on the efficiency of the filtration by mobile field laboratories. In each division there were and are some sixty water carts, each of which holds about 110 gallons. Nasmith and his co-workers attempted to get samples from all these in turn, to see whether the water had been treated. As all the sources of water supply in Flanders, with few exceptions, contain large numbers of bacteria, and as a properly chlorinated water contains very few bacteria, it was easy to tell from the bacteria and *B. coli* tests whether the water in the carts had been chlorinated, and these sample tests were adopted as a routine method of control. As there were sometimes eight divisions in Nasmith's area at one time, this water control meant a good deal of work.

Reports of all samples were sent to the A. D. M. S. of the division, who forwarded them to the medical officers of the units, with more or less caustic remarks should samples be bad. The officer in turn would get after the man in charge of the water cart, who usually had some more or less plausible excuse. The water details of the first Canadian division were the best trained lot of men Nasmith ever ran across. The very first day samples were taken from their carts, five weeks after the arrival of the division in France, they were all sterile, and there were no complaints about taste. It was an excellent example of what training could accomplish, for they had all been carefully trained in their duties in Canada and England. As the water details of any division change constantly, the efficiency of the treatment depended, to a great extent, on the constant supervision of the problem by the A. D. M. S., medical and sanitary officers.

Wells, springs, creeks, and ponds were also examined, and not infrequently samples from "springs" encountered while digging new trenches were sent in to be tested. The tremendous number of bacteria found in some of these "spring" samples Nasmith on several occasions reported as indicating the presence of some buried animal matter in the immediate vicinity of the springs, and a search proved these surmises to be correct.

Standing orders forbade the use of unboiled milk in the army, as well as uncooked vegetables, so that there was little danger from these sources. When one saw the peasants watering their vegetables with fresh house sewage, the reasons for such regulations were apparent.

Methods of Gas Warfare.—In the *American Journal of Pharmacy* for April, 1918, is a paper by S. I. M. Auld, dealing with the methods of gas warfare. After describing the several kinds of gas employed the writer goes on to say that up to the present time there has been no material brought out on either side that can be depended on to go through the other fellow's respirator. The casualties are due to surprise or to lack of training in the use of masks. The mask must be put on and adjusted within six seconds, which requires a considerable amount of preliminary training if it is to be done under field conditions. Among other surprises on the part of the Germans were phenylcarbylamine chloride, a lacrymator, and diphenylchloroarsine or "sneezing gas." The latter is mixed in with high explosive shells or with other gas shells or with shrapnel It is intended to make a man sneeze so badly that when he puts on his mask he is not able to keep it on. The sneezing gas, however, has not been a very great success. All bombardments now are of this mixed character. The shells used are marked with differently colored crosses, and definite programs are laid down for the use of artillerymen.

As regards the future of gas shells, it should be emphasized that the "gas shell" is not necessarily a gas shell at all, but a liquid or solid shell, and it opens up a whole sphere of organic chemistry to be drawn upon for materials. The material placed inside the shell is transformed into vapor or fine droplets by the explosion and a proper adjustment between the bursting charge and the poisonous substance is necessary. Both sides are busy trying to find something that the others have not used, and both are trying to find a "colorless, odorless, and invisible" gas that is highly poisonous. It is within the realms of possibilities that the war will be finished, literally, in the chemical laboratory. The Germans have not altered their type of respirator for some time, and it is not now equal in efficiency to the British or American respirator. The German respirator, even in its latest form, will break down at a concentration of 0.3 per cent. of certain substances. The German design has given more weight to military exigency, as against perfect protection than has the British. Another thing that weighs against changes in design is the fact that the German, already handicapped by the lack of certain materials, must manufacture 40,000,000 respirators a year in order to supply his Austrian, Bulgarian, and Turkish allies, as well as his own army.

In the British and American armies the respirator must always be carried with the equipment when within twelve miles of the front. Between twelve and five miles a man may remove the respirator box in order to sleep, but within five miles he must wear it constantly in the "alert" position, slung and tied in front. When the alarm is given he must get the respirator on within six seconds. The American respirator is identical with the British. The French have a fabric mask made in several layers, the inner provided with a nickel salt to stop HCN, then a layer with hexamethylenetetramine; it has no valve and is hot to wear. The French also use a box respirator, consisting of a metal box slung

on the back, with a tube connecting to the face mask; the latter is of good Para rubber and is provided with a valve. One disadvantage of this form is the danger of tearing the single rubber sheet. The German mask now contains no rubber except one washer; the elastic consists of springs inside a fabric, and the mask itself is of leather. It hardens and cracks after being wet and is too dependent upon being well fitted to the face when made.

Sarisbury Court Becomes Army Hospital.—Sarisbury Court, a famous hunting box of English Kings in Southampton, is being converted into a hospital for the accommodation of 3,000 American soldiers. The site of this manor house is a 186-acre park with a frontage on Southampton waters. In addition to the manor house, the large rooms of which will be used as wards, a number of tents of the Bossoneau type are being erected. The contract calls for the opening of 400 beds within six weeks. The construction work is under Captain F. Harper Sibley, formerly head of the Chamber of Commerce of Rochester, N. Y.

The Soldier's Chances.—Estimates based on the statistics of the allied armies show that a soldier has twenty-nine chances of coming home to one chance of being killed. He has forty-nine chances of recovering from wounds to one of dying from them. He has one chance in five hundred of losing a limb. He will live five years longer because of the physical training he has received. He is freer from disease in the army than in civil life, and he has better medical care at the front than at home. In other wars, from ten to fifteen men have died of disease to one from bullets; in this war one man dies from disease to every ten from bullets.

School for Deaf Soldiers.—The Division of Physical Reconstruction of the Surgeon General's Office has opened the first army medical school for the reconstruction of the defects of hearing and speech at Army Hospital No. 11, formerly Hotel Cape May, at Cape May, N. J.

The Status of Disabled Soldiers in Industry.—The office of the Federal Board for Vocational Education, to which Congress has entrusted the administration of the provisions of the Vocational Rehabilitation act, in order to obtain the advice and assistance of the State Compensation Boards and leading casualty companies of the country in working out the problems in connection with the employment of disabled men in industry, called a joint conference of such boards in Washington on July 25. The matter of rates of casualty companies on plants carrying accident insurance and employing disabled men who have been vocationally reeducated was discussed. In Great Britain the casualty companies have unanimously refused to advance the rates on employers of retrained soldiers, thereby refraining from adding any obstacles to the finding of employment for men refitted for industrial life.

Nurses Commended for Bravery.—A report has been received through official channels by the American Red Cross of the bravery of American Red Cross nurses during recent raids on hospitals. Major Moorehead, in command of one of these hospitals, says he cannot speak too highly of the efficiency of these nurses. He particularly mentions Miss Turnbull, the nurse in charge, Miss Elmyra Bears of Cambridge, Mass., Miss Louise Dildine of Columbus, Ohio, and Miss Constance Cooke of Berkeley, Cal. Major Murphy reports bravery on the part of Miss Natalie Scott.

Lieutenant William L. Staggers, with a medical unit of the British Expeditionary Forces, was wounded and captured several months ago, according to a card recently received by relatives in this country. Lieutenant Staggers was formerly an interne at St. Vincent's Hospital, Birmingham, Ala.

To Investigate Hazards to Women in War Industries.—An announcement made by Miss Mary Van Kleeck, Director of the Women in Industry Service of the Department of Labor, states that a committee of experts has been appointed to investigate the special hazards which war industry offers to women. The committee will visit various centers where women have been drawn into industries at work on war contracts to study the effect of such industries on the health of women employees. The committee will first visit Niagara Falls with a view to learning whether the chemical industries there offer such dangers to the health of women that their employment should be prohibited. Among those invited to serve on the committee are: Lieutenant-Colonel Harry E. Mock, Dr. Alice Hamilton of the Bureau of Labor Statistics, Dr. Richard M. Pearse of the National Research Council, Dr. J. W. Schereschewsky of the United States Public Health Service, and several members of the New York State Department of Labor.

Colored Nurses for Army.—The War Department has issued orders which will enable colored nurses who have been registered by the American Red Cross to render service for their own race in this country. These nurses will be assigned to various base hospitals at camps where about 30,000 colored troops are stationed. General Pershing was asked by cable whether the services of colored nurses could be utilized to advantage.

Ambulances Named for Quentin Roosevelt and Major Mitchel.—The American Poets' Ambulances in Italy announce that the last of their 112 ambulances provided for service on the Italian front will be inscribed in honor of Lieutenant Quentin Roosevelt and the 111th ambulance will be named for Major John Purroy Mitchel.

Outings for Convalescent Soldiers and Sailors.—Through the generosity of Dr. John A. Harriss, Deputy Police Commissioner of New York City soldiers and sailors convalescing in local hospitals are being given day water trips. Dr. Harriss has placed his steam yacht at the service of the Mayor's Committee on National Defense to be used for this purpose. The first trip was made on July 30.

Colonel J. M. T. Finney, M. R. C., U. S. A., chief consulting surgeon of the American Expeditionary Forces in France, returned to this country on July 27. It is rumored that he is here for the purpose of urging a higher rating for American army surgeons in France. No American surgeon ranks higher than a colonel, while allied medical officers rank as high as Major General.

MEDICAL RECORD.

BEARDS.

THIS subject is discussed from the esthetico-hygienic viewpoint, by Trombetta, in the *Giornale di Medicina Militare* for April 30. He suggests that *barba*, beard, has the same derivation as *barbarian*, etc., which is to be doubted, because the Greek *barbaros* is usually regarded as cognate with Latin *balbutire*, to stammer, with the connotation of unintelligible, in reference to those who speak a language unknown to the listeners. The term *gringo*, applied to natives of the United States by Spanish-Americans, has the same significance, and other examples of the same class could be quoted. The author traces the word *barba*, beard, through most of the Aryan languages, but there is nothing to show beyond doubt its original significance. It appears to have been corrupted from a root *bard*—thence German *bart* and English *beard*. It has rather a generic significance, for most nations have special words for hair on the upper lip, chin, and cheeks.

In tracing the history of shaving it should be sufficient to go back to the Greeks and Romans, upon whose civilizations our own is based. Beards were highly esteemed among the former up to the time of Alexander the Great, who was smooth shaven. One reason for the abolition of the beard among soldiers was the fact that it afforded the enemy something to lay hold of. At an earlier period the wearing of certain types of helmet and gorget had protected the beard. The Romans wore beards down to the time of the Gallic wars, while the Gauls, albeit barbarians, were smooth shaven save for the moustache. The antiquity of barber shops and razors in Rome is variously given by historians. Some have claimed that the first barber shop, at least in that part of the world, was opened in Sicily, in 300 B. C., while other authorities make this date far earlier or later. The Sicilian seems to have been the first barber, according to concensus of opinion. Naturally, one should not confound the barber and his razor with the hair dresser, wig maker, etc., which calling was naturally much older.

The youth of Rome began to shave during the age period 20-24, and did not abandon this practice until the age of 49. The first shave was a very solemn, ceremonious family event, for it signified that the adolescent was now a man. Not until the first century after Christ did the gilded youth of Rome return to wearing beards. Within comparatively few years the practice was again renounced, save by those who bore disfiguring scars on the face, and beards did not come in again until the time of Constantine.

The name Longobardi, or Longbeards, given to German invaders in the sixth century A. D., appears to show that full beards were not much affected in civilized Europe at that epoch.

The French were not partial to beards at any time, save perhaps during the Charlemagne period, although attempts were made at various epochs to introduce different types of hirsute adornment. In the days of Louis XIV all his subjects went clean shaven save the Calvinists, who wore beards. With the Revolution there was a great change, and all kinds of facial scenery were to be seen, especially among the artists. Under the First Empire and Restoration the soldier alone had the privilege of wearing moustache and imperial, and the beard came to distinguish the bohemian and the Capuchin monk. The fashions in Italy agreed closely with those of the French.

A sort of legend has grown up that free people are free to wear beards, and the unkempt facial growth of the traditional Anarchist may represent this symbolism. Very different is the notion of the right to go clean shaven on hygienic and esthetic grounds. The author now goes extensively into the long series of eruptive conditions consequent upon the custom of wearing beards, and which either do not attack the smooth-shaven, or attack him in a mild, readily controllable form. Impetigo, true sycosis, and parasitic ringworm are the chief offenders, or were until the outbreak of the present war, when the crab louse, or *Pediculus pubis*, began to infest the beard of the soldier.

The author styles May 27, 1916, the fatal day for the beard in Italy, for on that date the War Department issued to officers and privates a memorable recommendation to remove henceforth this feature from the face, in which it is implied that the beard is a barbarism and anachronism.

THE ATHLETIC OLD MAN.

PERHAPS it is that as we grow older we are too content to accept the rôle society accords us. We are too ready to exchange baseball for croquet, boxing for billiards, and tennis for golf. It is true that in all the more strenuous forms of competitive athletics youth will be served—the baseball player and pugilist are old at 30—but that is no reason why one should sink contentedly into a lethargy at middle age and impotently watch his waist increase and his breath decrease as the years go by.

In these days of omnipresent trolleys and cheap motor-cars walking is becoming a lost art. It has become automatic now to consider our objective—is it more than a few blocks away? If so, we look

about for some means of conveyance. We pay money, hang to straps, breathe vitiated air and have our toes trodden on, to have ourselves transferred ten blocks farther on, ten blocks which we might walk in ten or at most fifteen minutes, with the greatest benefit to mind and body. An English physician, Sir Herman Weber, has recently called attention in the pages of the *British Medical Journal* to the benefits of walking and other exercise in promoting longevity. His views command the more respect when we learn that he himself is in his 95th year. He calls attention to the favorable influence which regular and vigorous walking has on metabolism, a fact first pointed out by Hippocrates. Even the aged, he says, can take long walks through hilly country with benefit. The exercise should be regular, however, and not dependent upon weather conditions, for old persons do not resume interrupted physical exercise with the same ease as the young. Many other forms of muscular work can be substituted for walking by those whose tastes lead them that way, horseback riding, hunting, golf, and so on. They must, of course, be governed by the effect which the exercise produces.

Dr. Weber does not stress it, although his intellectual activities are sufficiently illustrative, but equally prominent in promoting longevity should be placed the constant cultivation of the mind, the maintenance of intellectual enthusiasm and receptivity towards fresh impressions. Cato learning Greek at 80 is the conventional example which at once rises to the mind, but other and more modern instances will be recalled if we begin to cast about. De Morgan, after a long and not obscure career as an artist, began to write a novel at 60 and published it at 65. From then on until an unkind fate cut him off in his prime at 80 he wrote six more books only one of which was without merit, and established his fame as a novelist far above that which he had enjoyed as artist.

So, although as we pass on from the infantile twenties, through the green thirties, and past the crude forties into the experienced fifties and mature sixties, we begin to experience the pleasures of old age which, Samuel Butler tells us, are more soul-satisfying than those of youth. "Who is under fifty?" says the French Academician. "A few hobbledehoys, perhaps." While we may not be able to beat our neighbor's son at tennis, or run a hundred yards in ten seconds, let those with sporting proclivities remind us that Mike Donovan, at 60, fought six rounds with the then champion of his class and had none the worst of it. If such prowess is not ours, at least we can take regular exercise, keep our minds open to all that is new in science, to art, and all that is worth while in the world and hold our own in the realm of intellect to the last.

SOME PHASES OF MALARIA.

Of all tropical or semitropical diseases malaria stands upon an undesirably lofty pedestal. According to a well-known medical historian the malady was chiefly responsible for the decadence of Greece, and although effectual preventive measures are now known and put into practice malaria still holds its place as preeminently the disease of the tropics. It goes without saying that during the war a good deal has been heard of malaria. In fact, in campaigns undertaken in torrid and swampy lands in which mosquitos abound malaria has invalided and incapacitated more fighting men than shot and shell. Especially has this been the case in East Africa, a country of sinister reputation as regards tropical diseases.

Capt. W. F. Wicht, of the South African Medical Corps, writing in the *Dublin Medical Journal* for May, 1918, points out that in East Africa the worst enemy is the "germ" without the "Hun," and goes on to say that he does not think he is exaggerating in any way when he states that of the total number of casualties on the East African front over 80 per cent. are medical cases, and a very large proportion of these cases are due to malaria. Wicht also states that owing to the energy displayed by members of the Army Medical Corps the treatment of malaria has been practically revolutionized and furthermore that some very important points which have hitherto been unknown with regard to the malady have been brought to light.

He says that malaria may be divided into two main classes, benign and malignant, the treatment of both of which is on similar lines. So far as therapeutic treatment is concerned, he pins his faith to quinine and arsenic or a combination of the two, and, moreover, does not hesitate on account of the fear of producing blackwater fever to give quinine in massive doses.

Energetic treatment of this description should be begun at once, or the disease may lapse into a chronic state, when the results of treatment are problematical. However, as quinine in large doses is very liable to upset the digestive organs, it is best to prescribe hydrobromide of quinine in smaller doses at shorter intervals.

The most frequent complication of malaria is splenic enlargement, which can be generally overcome by rest in bed and perseverance in antimalarial treatment. Tachycardia and temporary valvular lesions are nearly always present, and in this connection Wicht advises the patient against smoking too much, pointing out that smoking affects the malarial subject to a much greater degree than one would expect. As is well known, anemia is quite a common complication. Quinine is in itself a fairly powerful hemolytic. As in all cases of anemia arsenic is here the sovereign remedy, and this drug in conjunction with good nourishing food, will usually work wonders at this stage of the disease. For malarial dysentery quinine and arsenic should be administered. Lastly, Wicht draws attention to the fact that all those who suffer from chronic malarial infection appear to be very liable to rheumatic infections.

SUDDEN DEATH IN RELATION TO RESIDUAL ADRENALIN.

Sampaio, writing in the *Brazil-Medico* of March 16 and 23, refers to the work of the Italians Cavidalli and Leocini in regard to the amount of adrenalin in the adrenals of various cadavers, with especial reference to the mode of death. The amount in question was distinctly larger in agonal forms of death. If this discovery could be properly formulated it could be utilized forensically. Professor Freire of Bahia, who is at the head of a unique institution for medicological research, the Nina Rodrigues Institute, requested the writer to take up the problem at first hand. The Italian technique was used, as follows: The cortex of the two glands is triturated in saline solution, slightly acidulated with HCl. The real extraction is effected with saturated sodium chloride solution, which is heated to boiling to complete the extraction. The filtrate is then tested for adrenalin content with a few drops of potassium ferricyanide and ammonia.

The test is purely qualitative or colorimetric. The number of shades corresponding to adrenalin content is considerable, ranging from greenish or golden yellow to dark red. Control colors are used, and for convenience three divisions are made of slight, medium, and intense coloration. The author has examined in this way the adrenals of 100 cadavers. Intense reactions were obtained in both acute and slow death, but predominated in the former. At the other extreme a mild reaction was not once seen in sudden death. It must be borne in mind that the subject of adrenal death from exhaustion of the adrenals, such as might conceivably occur in shock, is not at all under consideration in this research. The mode of death of most interest is essentially that inflicted suddenly, perhaps in the midst of vigorous health, as in suicide, accident, and homicide, but not necessarily occurring after intense effort, as in death in battle. At the other extreme is the ordinary deathbed of disease, including chronic disease, such as pulmonary tuberculosis. It is conceivable that in both types of death the amount of adrenalin might show wide variation, and it is the more striking that in no case of gradual death was there a normal amount of adrenalin remaining in the glands. This suggests at first sight a relationship between lingering death and low blood pressure, and conversely that in sudden death, as in apoplexy and uremia, the blood pressure may be high. In most deaths which demand medical inquiry, however, there is no antecedent factor which bears on the blood pressure at the time of the death wound. Hence only in concealed deaths would the test possess value. The question then arises as to the action of putrefaction on the adrenalin content of the adrenals. The Italian authors answer this question satisfactorily in showing that the adrenals resist putrefaction in a high degree, and that no changes are in evidence in respect to adrenalin content for at least 72 hours after death.

Obviously, some quantitative analysis must be made as controls of color tests, and in this way shades of color can be made to harmonize with definite quantities per 1,000 of adrenalin in solution. The limits of content are 0.01 and 0.50 per 1,000 parts of solution. A suicide with firearms presented 0.33; a homicide victim, 0.16; phenol poisoning, 0.50; rupture of a thoracic aneurysm, 0.25; drowning, 0.50; death following rupture of middle meningeal, 0.50; sudden death in coronary artery disease, 0.25. Opposed to these we find gradual decrease from phthisis, 0.01; another case of the same, 0.08; a third case, 0.04; a fourth case, 0.03, etc. There are types of slow death, however, in which the patient's illness lasts but a few days, in which the content runs about as low; in other words, it is not a mere question of long invalidism, but rather of absence of any factor which can produce agonal or violent death. Thus, in death four days after postpartum hemorrhage, the content was 0.04. In some slow deaths in which there was reason to suspect the presence of an agonal factor, the content was higher, as 0.12. Once established, the technique is not burdensome, and the test could be tried out in municipal pathological laboratories.

Enuresis.

Bed-wetting is a trying enough condition in the case of the individual child in the home, but in an institution caring for a great many it becomes quite a serious problem when present in a large proportion of the children. Formerly, whether occurring in the home or in an institution, the condition called for disciplinary measures, on the assumption that the child was wholly responsible. At present, however, it is the consensus of opinion that enuresis is entirely a medical problem, not within the individual will of the child to prevent, nor influenced by punitive measures. Even when no definite pathological condition is found to account for the local manifestation, it is apparent that enuresis often accompanies an inferior mental or physical constitution. It is perhaps very common in the precocious but nervous child, in whom the degree of mental precocity would seem to rule out wilful bed-wetting. However, the irritability of the nervous system in children of this type causes an undue reaction to any stimulus, and they have little control over any of their functions. Of course, there are tangible local conditions that cause incontinence in the bladder, but these do not constitute the problem of bed-wetting. On the other hand, as a purely local condition but which must cause the great majority of cases of enuresis, anomalies of the foreskin of male children and adhesion of the rudimentary one in female children hold the first place. When this is recognized as the etiological factor, circumcision seems to cure about 80 per cent. of these cases. There is now no longer any doubt that circumcision in the male child is a prophylactic measure of greatest importance not only in the prevention of this condition but in the prevention of many bad habits. As a therapeutic measure in many backward children who display no basis for mental deficiency, it can be compared with operations for the relief of obstructions to respiration. But although these physical and nervous con-

ditions are the basis for the bed-wetting habit, there are many exciting causes that need attention in order to prevent the attack or as after care in cases having received the active treatment indicated. Any circumstance which encourages relaxation of the sphinctors during sleep encourages bed-wetting. Sleeping in an overheated room, in an overwarm bed, or on or under a feather bed is likely to cause bed-wetting in a child so inclined. Also a child of this type sleeping with an overfilled bladder will soon lose the power of resistance of the compressor muscle, especially since he already has poor control over it. It is for this reason that fluids of any kind must be interdicted to such a child after about 6 o'clock. And it goes without saying that the awakening of the child during the night to empty its bladder will prevent the annoyance of the bed-wetting until such time as the appropriate therapeusis makes this unnecessary. Drugs usually given in this condition seem of doubtful value, except such as are tonics to the entire organism. Unless the medical point of view is accepted in relation to the cause of enuresis, and treatment is instituted accordingly, little improvement can be expected. On the contrary, the punitive measures usually adopted can but aggravate the condition.

News of the Week.

Ask Action on Health Program.—The War Service Committee of the American Hospital Association has appealed to the Treasury Department for prompt action on a comprehensive program of health conservation adopted last winter by a group of prominent sanitarians, which it claims is needed as a war measure. This program was referred to the Treasury Department on July 1. It asks for the appointment of an administrative head to be known as the Assistant Secretary of Health or perhaps the Health Administrator, to hold his place for the duration of the war. Among the important features of health control formulated in this program are the following: The establishment of standard procedures for the control of communicable disease, including reporting, diagnosis, treatment, and sanitary supervision, and the adoption of these standards by local authorities. Particular attention is to be paid to hookworm disease, malaria, typhoid fever, tuberculosis, and the communicable diseases of childhood. A comprehensive program for the hygiene of war industries is to be prepared and put into effect. Standards for maternity care and for the care and preservation of infants and children should be prepared and promulgated. A plan should be prepared and put into effect for the after care of men enlisted or drafted and subsequently rejected or discharged on account of mental or physical defects, and should include extension of facilities for the sanatorium and home care of tuberculosis victims and for hospital and home treatment for mental defectives and drug addicts. To insure the quality and reasonable cost of essential drugs and biological products, standards of potency and of manufacture should be developed and enforced. Steps should be taken for the national registration of deaths, births, and cases of preventable diseases. A program should be prepared for maintaining an adequate supply of properly trained sanitarians, physicians, and nurses during the war. The means for the extension of existing facilities should be provided by the Government.

Major Caldwell's Estate Goes to Columbia University.—The bulk of the estate of the late Major Eugene Wilson Caldwell, Medical Reserve Corps of the United States Army, amounting to about $150,000, is to go to Columbia University on the death of his wife and mother. The sum which the university will receive is to be known as the "Eugene Wilson Caldwell Fund" and is to be used for general educational purposes. Major Caldwell bequeathed his laboratory and its contents, together with the good will of the establishment, to his two friends and collaborators, Dr. Harry M. Imboden and Thomas Riker. He has requested them to continue the work upon which he was engaged.

State Board of Regents Gives Women's Hospital Alumnæ Hearing.—The State Board of Regents, at a meeting in Albany on July 22, gave a hearing to representatives of the Alumnæ Association of the New York College and Hospital for Women. After hearing the argument of the Alumnæ Association, the Board of Regents ordered the Board of Trustees of the Hospital to submit a detailed account of the institution's finances to the Alumnæ Association. The Alumnæ Association announces that it has met with marked success in its effort to raise $50,000 to maintain the Hospital for Women. If the women gain control of the hospital they will offer it to the Government for war needs.

Examining New York Babies.—The Health Committee of the Mayor's Committee on National Defense has begun the work of making physical examinations of all children under five years of age in Greater New York. Dr. S. Josephine Baker is directing the work and has established clinics in all boroughs. More than 1,000 nurses, welfare, and social workers have volunteered their services, together with 300 physicians, who will work at least two days a week free of charge. There are more than 100 clinics for this purpose in Manhattan alone. During the week beginning July 15 some 3,000 babies were examined. There is a total of over 600,000 children to be examined.

Bellevue Hospital Reports Fewer Cases of Alcoholism.—Dr. Stephen P. Jewett, head of the alcoholic ward of Bellevue Hospital, finds that during the first six months of 1918 they have treated about 1,079 cases in the alcoholic ward of Bellevue Hospital as against 3,375 cases treated during the corresponding period of 1917. Almost all the cases treated since last winter have been men ranging in age from 35 to 60 years and the majority of these were cases of chronic alcoholism. This decrease is believed to be due to the fact that much of the money that formerly went over the bar is now devoted to the purchase of Liberty Bonds and Thrift Stamps.

Penal Servitude for Dispensing Narcotic Drugs.—According to the decision of the United States Court of Appeals, a medical man recently convicted of dispensing narcotic drugs has been sentenced to serve a term of five years in the Leavenworth penitentiary and pay a fine of $12,000. At

the same time the court held a part of the anti-narcotic law dealing with the misuse of Government order blanks unconstitutional. Possibly this decision may affect the status of a number of persons now serving sentences for violation of this provision.

Pressing Need for Tuberculosis Hospitals.—The National Tuberculosis Association has issued a statement setting forth the pressing need for more tuberculosis hospitals. This statement claims that hospital facilities are needed to accommodate more than 1,000,000 tuberculous persons. In its efforts to provide the required increase in hospital facilities the association is cooperating with the capital issues committee of the Federal Reserve Board.

Civil Service Positions Open to Physicians.—The Civil Service Commission of the State of New York announces the following positions in the State Department of Health for which application must be made before August 21, 1918: *Hospital and Dispensary Organizer and Inspector*, open to men only, and carrying a salary of $2,500. The applicant for this position will be required to organize venereal clinics in different parts of the State and to advise as to their proper administration. *Lecturer on Social Diseases.* This position is open to both men and women and carries a salary of $2,500. Preference will be given to those having a general knowledge of venéreal diseases. *Assistant Physician.* This position is open to regular or homeopathic physicians and is for the purpose of providing eligibles for the position of assistant physician in the State Hospitals and other positions of a similar nature in various State and County institutions. This position carries a salary of $1,200 with increase. *Resident Physician* for State Agricultural and Industrial School, Monroe County, N. Y. This position is open to men only and carries a salary of $1,500 to $2,000 and maintenance for the physician and his family.

Medical Society Establishes Fund for Research.—The Tri-State Medical Society, at a meeting held at Freeport, Ill., on July 9 formulated plans for the establishment of a $20,000 foundation for the purpose of making the society a permanent and independent body and for the furtherance of research work. The fund is to be raised by voluntary subscription, and thus far a number of physicians have made substantial contributions.

Epidemics in Russia and Germany.—A cablegram under date of July 27 states that during the past twenty-four hours 111 cases of Asiatic cholera have been officially reported in Petrograd. The epidemic seems to be steadily on the increase, and the waters of the Neva, which are used for drinking purposes, are filled with cholera bacilli. According to official despatches received from Switzerland, several epidemics are sweeping Germany. Both typhoid and typhus fever are said to have appeared in epidemic form in Berlin and the German censor has forbidden the publication of news on the increase of influenza, though it is known that the disease has made serious ravages. Malaria is reported in the Grand Duchy of Baden, where the disease has been disseminated by troops from the Balkans.

New York City Hospitals Need Nurses.—In order to solve the problem of obtaining sufficient nurses for bedside attendance in the city hospitals and for the Bureau of Child Hygiene and Preventable Diseases of the Department of Health, the Municipal Civil Service Commission considers asking physicians to release their office nurses for half a day for this work. The Civil Service Commission will receive applications for examination from nurses who have completed their course of training but have not obtained State licenses. Married nurses will also be appealed to to take the examination.

Decline in Infant Death Rate.—An infant mortality survey by the New York Milk Committee has been made public which shows that the efforts of the various agencies engaged in infant welfare work, as well as the work of the New York Milk Committee has been effective in reducing the infant death rate in this city. The survey covers the calendar year of 1917 for which the death rate was 88.8 per 1,000 living births. In 1907 the rate was 135.8. The number of infant deaths under one year of age for the year 1917 was 12,568 as against 16,000 in 1907. The report of the Milk Committee also contains figures from 163 of the largest cities which show with one exception decreases in the death rate. The lowest mortality for cities of 100,000 is found at Omaha and Seattle, which have 59.2 and 59.4, respectively. The low rate for the country is found at Alameda, Cal., where the rate is 40.7. Other cities of 50,000 that are only a fraction above this level are Brookline and Everett, Mass., and La Crosse and Berkeley, Cal. The highest mortality of the country is at Nashville, Tenn., which has a rate of 182.2 with a population of 110,364. Chicago exceeds New York in infant mortality by nearly 18 points and Philaphia by 21 points. Other cities having an infant death rate of over 100 per 1000 living births are Baltimore, 119.3; Pittsburgh, 116.2; Detroit, 103.6; Buffalo, 103.7; New Orleans, 113.5; Jersey City, 113.8; Louisville, 110.5; Syracuse, 101.9; Birmingham, 147.5; Memphis, 145.7; Richmond, 134.5; Fall River, 153.8; Grand Rapids, 134.9, and Albany, 103.2. Boston has 98.9.

Obituary Notes.—Dr. THOMAS N. GRAY of East Orange, N. J., died of apoplexy, on July 23, at the age of 65 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1879, and for some years city physician of Orange. He was president of the New Jersey Academy of Medicine, vice-president of the New Jersey Pediatric Society, secretary of the Medical Society of the State of New Jersey, chief of staff of the Bureau of Tuberculosis of Newark, and a member of the Medical War Examining Board of Essex County.

Dr. ENOCH P. LAWRENCE, a graduate of the New York University Medical Department in 1880, died at his home in Flushing, L. I., on July 26, aged 62 years. He was consulting physician to St. John's Hospital, Long Island City, and physician in charge of St. Joseph's Orphanage.

Dr. E. W. SANFORD of the Johns Hopkins Medical Faculty, a graduate of Johns Hopkins University, died at Centreville, Conn., on July 2, of blood poisoning produced by accidental inoculation while engaged in research work for the Government. He was 25 years of age.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

NATIONAL BABY WEEK IN LONDON—REFORM OF THE INDIAN MEDICAL SERVICE—EPSOM COLLEGE—BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

London, July 3, 1918.

THE first week in July is being devoted to propaganda work in connection with child welfare in its broadest sense, including all work done for the care of mother and child during pregnancy and the immediately succeeding stages. The pronouncements and the propaganda of various agencies more or less connected with so wide a movement have been much strengthened by the presence in the city of well-known advocates of Child Welfare from other countries, notably Dr. Palmer Lucas of the American Red Cross, Dr. Truby King, well known for his devoted activities in New Zealand, and Judge Neil of Chicago. Most of the leading English organizations for the care of mother and child are now represented in a National League of Health, Maternity and Child Welfare, while a new body, The Council for the Unmarried Mother and Her Child, has been included in the group. The arrangements for "Baby Week" comprise an exhibition giving practical illustration of the efforts made in diverse directions by all these organizations, and this exhibition afforded point to a series of conferences and informatory addresses delivered within easy reach of it. The arresting fact about the activities of "Baby Week" has been the absence of cant and slushy sentimentality; that the unmarried mother is the product of far-reaching social circumstances and not of essential or personal immorality has been recognized; and this, the medical and hygiene view of the situation, has been accepted also as the Christian view by the congressists as a body. The terrible experiences of the last three and a half years have aroused the public in unmistakable manner to the value of human life, and to the absolute necessity of conserving, and conserving at their fittest, the generations now arising or yet to be born. Public support is being obtained in a marked manner for all the associated movements. Government officials are not waiting to be pressed before they lend invaluable cooperation. Problems in connection with infant life, of venereal and hereditary disease, of overcrowding and unsuitable habitation, of defects in educational systems, of improper occupation of children—to mention only those that occur immediately—are now obtaining a free discussion which must have in the near future a valuable outcome. Public questions are being faced and moral problems bravely solved. It is realized that for fruitful action actual knowledge of the attendant causes or underlying conditions of infant mortality must be obtained, and that the knowledge must be discriminated even though it may be shocking. As a result of publicity the more enlightened of the populations have already realized that health is cheaper than disease, and that a high infant mortality is, if nothing worse, a piece of rank extravagance. Money will follow, and practical hygiene be made possible.

A deputation from the British Medical Association has been received by Mr. E. S. Montagu, the Secretary of State for India, who expressed himself willing to discuss the possibilities of reform in the Indian Medical Service where the conditions have been for a long time so entirely unsatisfactory that the personnel of the service is in danger of deterioration as well as being permanently below the requisite numbers. Sir Clifford Allbutt, the president of the British Medical Association, introduced the deputations, and from his experience as Professor of Medicine in the University of Cambridge he was able to state personally that the Indian Medical Service does not possess attractions for the best class of young medical men, in that the career offers no opportunities for research work, so that the rewards in it are not reaped by the more scientific representatives of the profession. Evidence was given by various officers in the India Medical Service of the discontent existing among the officers of the Service, owing to default in the regulations for obtaining leave, to difficulty in retirement, to neglect of measures for the adjustment of pay, and to unfairness in promotion, the last grievance being affected by the presence in India of two corps, namely, the India Medical Service and the Royal Army Medical Corps. Allusion was also made by different speakers to the restrictions placed upon the officers of the Indian Medical Service with regard to private practice. The representations of the deputation amounted to a warning to the Secretary of State that unless the conditions under which the officers of the Indian Medical Service worked are substantially bettered the Indian Empire will go short of doctors, so far as a European service is concerned. Mr. Montagu, who has recently been in India, agreed in substance with the arguments placed before him, and acknowledged that it would be folly on the part of the Indian Government not to be ready with more attractive offers to the medical profession in India, as soon as the war was concluded. He pointed out only the truth when he said that recent improvements had been effected in the Service, for the rates of staff pay in the field have been raised and a scheme has been devised to prevent the supersession of the officers of the I. M. S. by these of the R. A. M. C. But none the less the emoluments of the Indian Medical Service are inadequate, and the circumstances of professional life within its jurisdiction are attended with much friction. This Mr. Montagu admitted, and in the matter of private practice he thought that greater opportunities for advantaging themselves and others should be extended to officers in the I. M. S., so long as the attention upon their personal clients or the claims of individual research did not interfere with the discharge of their public duties. But he went on to touch upon the most difficult factor in the case, namely the relations which should exist between indigenous medicine and the State-supported practice of medical officers sent out from the mother country. The situation here is, of course, a grave dilemma and it has been recognized as such for a long time. A statesmanlike attitude is required both on the part of the Government authorities and on that of the medical profession if the difficulties of the dilemma are to be removed or checked instead of being allowed to increase until a real *impasse* is reached. Indigenous medicine is

represented now in India by many highly qualified and highly endowed native practitioners but these men cannot enter the Indian Medical Service from their own universities, but only after admission to the British Register, although the Indian universities are staffed by the scientific flower of the I. M. S. If the teachers are good—and they are good—it may be asked why cannot the pupils receive the full reward of education? On the other hand, if for the officers of the Indian Medical Service inducements to lead a hard life away from home are not provided, how is the good material to be obtained for staffing the native universities and maintaining in India the proper scientific level of education? Mr. Montagu said that one of the governing principles for future action in the matter which he had in his mind would be to provide increased opportunities for Indians to enter the Indian Medical Service on equal conditions with equal opportunities of promotion. He has thus recognized one horn of the dilemma, though not the one to which the deputation possibly desired particularly to draw attention. The probability is that for some time to come in India there will be found room for and need for a British Service, but that British Service will have to be a harmonious one and must not consist of two separate corps competing against each other. Side by side with a properly paid and harmonious British Service there should arise a well-educated Indian medical profession to whom proper opportunities must be given for entering a State service and so obtaining a *locus standi* in competing for State posts. But the development of the Indian medical profession depends, at any rate for some time, upon the maintenance of a thoroughly good State service, and this cannot be obtained unless fair conditions and good pay are attached to the career.

Epsom College is the English public school to which is attached a medical foundation under which pensions are granted to aged members of the medical profession or to the widows of medical men, and (far more important) under which also a gratuitous education of the highest class, together with maintenance, clothing, and even pocket money, are provided for the sons of necessitous doctors. The medical foundation is under Royal patronage and out of this fact a very annoying complication has arisen, for the college is sometimes known as the Royal Medical Benevolent College, while there is an excellent medical charity known as the Royal Medical Benevolent Fund. When testators leave their money to the Royal Medical Benevolent *Society* or *Association*, neither of which bodies has any existence save in recurring wills, which charity do they mean to benefit, the College or the Fund? Considerable sums of money have been spent in litigation and lost to medical charity by the inability of the College and the Fund to come to terms about doubtful bequests, but at the last meeting of the governors of Epsom College, a more reasonable spirit was manifested. The College may agree to the formation of a joint arbitration committee to decide the destination of legacies without recourse to law, and the Fund have already shown willingness to accede to a scheme of this sort.

Those responsible for the collection and distribution of this fund are making strenuous efforts to obtain money. The substantial sum of £20,000 was raised shortly after the outbreak of the war, and, when the needs of the necessitous Belgian doctors and pharmacists who had taken immediate shelter on English shores with their dependents had been dealt with, the rest of the money was sent by weekly installments of £200 to Belgian doctors and pharmacists in Brussels. The money was confided for transport to Belgium to Mr. C. Hoover, then the director for Europe of the Commission for Relief in Belgium, and through Mr. Hoover it reached the hands of a representative Committee of Belgian medical men and pharmacists sitting in Brussels and taking weekly evidence as to the most necessitous cases. The sum of £200 a week was decided upon by the Executive Committee of the fund because such an expenditure, though commenced early in 1916, did not imply exhaustion of the money collected until the end of 1917, by which time it was hoped that the last stages of the war would have arrived, or be arriving, and the result of this optimistic calculation was to leave the fund at the end of 1917 with only £600. Though fully aware that the time and the occasion were not propitious for the collection of money, the committee, which is representative of all classes of the medical profession in Great Britain and Ireland, made a second appeal at the beginning of this year* and are now following up that appeal in a vigorous manner. Something like £2,500 have been received in the last month or two, and, if this rate of subscription can be continued, the Fund should be enabled for at least one more year to continue its monthly subsidies to Belgium, and never did the Belgian doctors and pharmacists more sorely stand in need of material and moral assistance. Professional men in England know full well how generously through the Commission for Relief in Belgium the American people have assisted oppressed Belgium, and in that assistance the Belgian doctor and pharmacists have taken their share; none the less, if any American doctor or pharmacist is moved to subscribe to the Belgian Doctors' and Pharmacists' Relief Fund, I may mention that the chairman of the fund is Sir Rickman Godlee, Bart., 19 Wimpole Street, London, W.; the Hon. Secretary Dr. S. Squire Sprigge, "The Lancet" Offices, 423 Strand, London, W. C.; the Hon. Treasurer Dr. H. A. Des Vœux, 14 Buckingham Gate, London, S. W., and that subscriptions will be gratefully received by any of them.

OUR LETTER FROM PARIS.

(From Our Own Correspondent)

AN EMERGENCY HOSPITAL—WOMEN SOLDIERS—THE AMERICAN AMBULANCE SERVICE—Y. M. C. A. EDUCATING THE ARMY.

PARIS, June 18, 1918.

THE business-like organization of the American Red Cross in France was recently exhibited in its response to a call for an emergency hospital. A request from Dr. Blake came to the headquarters in Paris to provide a 500-bed tent hospital, to which there might be immediately transferred the patients of the Fracture Hospital menaced by constant air raids in Eastern France. Fortunately there was a hospital available not far from the point to be

*MEDICAL RECORD, March 30th, London Letter.

evacuated in a town in the American Army zone, where the Red Cross has warehouses for the purpose of meeting just such emergencies. Two men from Paris headquarters left Saturday night and on Sunday morning joined forces with the experts in charge of the warehouse, where the hospital tents were stored. By Sunday night the equipment was packed ready for shipment after a hard day's work. Help was given by Russians from a neighboring camp. The head of the warehouse is Senator Griggs of Minnesota, and through his efforts permission to move material within the Army zone was quickly obtained. Therefore by Monday morning the first freight train went through.

A 500-bed tent hospital consists of 25 tents about 20 by 60 feet in size, and each tent contains 20 beds. The tents are constructed with an outer and an inner canvas wall, having an air chamber between, which makes them suitable for cold or warm weather. In addition to the 18 windows furnishing plenty of light there is top ventilation. All the tents are connected by a covered corridor, and when the hospital is complete it covers an area about the size of a football field. From Saturday to Tuesday evening was the exact time that elapsed between the first telephone call received at Red Cross Headquarters in Paris and the arrival of the hospital at its destination where five hundred patients can be cared for. A piece of work like this shows what the Red Cross can do in an emergency.

Much has been written of the competent way in which American men are handling the emergency situations that are arising daily, but little has been said of what the women are doing in such moments of crisis. Miss Caspairs, Miss English, and Miss Wilde, of the American Fund for the French wounded, have been highly commended recently for their efficient work in the Courneuve catastrophe. They immediately volunteered their services and received permission to drive their autos to the scene of the disaster. They transported the homeless to places of shelter. Miss Caspairs used her auto to carry the refugees to Paris, while Miss Wilde, nobly refusing several shyly proffered "pourboires," established a transportation service over the dreadful roads to Le Bourget, where many of the refugees had friends who could take them in. This is only one of a dozen of instances where the young ladies of the A. F. F. W. have accomplished the same work as the men, and it is not surprising that the organization is proud of them. They drive the supply autos to the 4,000 hospitals that are on the books of the fund and they visit every corner of France to distribute the gifts that are most needed. In fact, it is women almost entirely that compose the staff of the American Fund for the French Wounded, which has become one of the most important and far-reaching American charity organizations in France.

The United States Army Ambulance service with the French army has received the announcement of the citation of Lieutenant William E. Westbrook, commanding Section 621, which speaks of his bravery and courage during a gas attack, when he evacuated a number of men who were suffering from the effects of gas. All the reports from the front recently have remarked on the excellent work of the ambulance service during the heavy fighting with but few losses. An ambulance driver, Mr. Carey Richards Evans, of S. S. U. 523, was killed last week while on duty. Mr. Evans, with another driver named Brook, was preparing to leave a "poste de secours." Evans was assisting the stretcher bearers in loading the wounded into his ambulance and Brook remained at the wheel, when a German shell exploded, killing Evans almost instantly. Brook was not hurt.

Evans was from Columbus, Ohio, and was one of the new men of the service who had trained at Allentown, Pa. He had a military funeral and was buried near the spot where he had fallen. In reporting his death his commanding officer said that "his wonderful personality made him an important cog in the crown gear of the esprit of the section, so well expressed in the editorials of the section paper." He also said that Evans was one of the most fearless men that he had ever known and that he died with a smile on his face, a man and an American to the very last. The morale of the men of the service is said to be splendid. It seems that this casualty has made them realize that their service is a man's job. They have behaved soundly and sanely as men and Americans, and the section to-day is a better one than it ever was.

Dr. John Finley, president of the Board of Regents of the State of New York, has accepted the invitation of the Y. M. C. A. to become chairman of its Army Educational Commission. The commission will undertake the carrying out of an extensive program in the American Army during the war and prepare for larger work during the period of demobilization. Its main interests in the immediate future will be in connection with the teaching of French and providing information concerning French institutions, causes of the war, and the issues at stake between the Allied nations and Germany. Illustrated lantern lectures will be given on various subjects and instruction in mathematics for promotion examinations, etc. The arrangements for this educational work under the auspices of the Y. M. C. A. have met with the approval of the Commander-in-Chief, having been outlined in a report presented to him by Mr. Anson Phelps Stokes, secretary of Yale University, who has been attending to the preliminary organization of the work.

During the fifteenth week of this year 966 deaths were registered in Paris; there were 1,053 during the preceding week and the average for the season is 1,003. Typhoid fever caused 2 deaths, measles 10, whooping cough 16, diphtheria 6, and infantile diarrhea 12. There were 32 violent deaths and 9 suicides. In Paris 367 marriages were celebrated. The birth of 653 children were registered; they comprised 343 boys and 310 girls.

116, Avenue des Champs Elysées.

Epidemic of Medical Erysipelas.—Maranon saw 70 cases of this affection (uncomplicated by traumatism) in the service of one hospital. The victims consisted of food producers, such as fishermen, truck growers, etc., and venders; it was therefore inferred that the *Streptococcus erysipelatis* was diffused by food articles and reached the nasal fossæ by autoinoculation. Of interest was the association of much streptococcus sore throat and cases of infectious pseudorheumatism.—*El Siglo Médico.*

1. The Massachusetts Medical Society. The Shattuck Lecture—Shell Shock and After.—E. E. Southard discusses the term *neuropsychiatry*, evolved since the war and now definitely accepted, a Division of Neurology and Psychiatry having been established at Washington by the Surgeon-General. The majority of shell-shock cases are instances of functional neuroses rather than organic disease of the nervous system but puzzling admixtures of these are by no means uncommon and, moreover, organic disease of the nervous system has always been capable of imitating the phenomena of functional disease, a fact which has been absolutely proven in the present war. Though the definition of neurosis has been mainly by negatives, the work of Charcot and Babinski—with the remarkable concept of the so-called physiopathie of the latter—has yielded a number of positive features from the clinical standpoint. The diagnostician, however, remains face to face with many difficulties. For example: shell bursts and other detonations can produce hemorrhage in the nervous system and in various organs without external injury, and accordingly the hypothesis of focal structural damage to the nervous system or its membranes has to be raised; or there may be a combination of structural and functional disease. The greater number of cases of alleged shell-shock without external wound prove to be functional. There is also a group of war neuroses—especially in cases of ear injury—in which the functional disorder surrounds the organic as a nucleus. Such "periorganic" neuroses, however, are no proof that the neuroses are organic in nature. The process of such a peritraumatic disorder is, nevertheless, a functional process. Schuster claims a hypersensitive phase after shell explosion, when the patient is particularly subject to hysterical symptoms. Reported cases show that the same effect may be seen in the absence of any obvious shell explosion, emotion, or somatic disorder. The process appears to pick out the weak spots in the patient. Southard refers to the value of shell-shock data of the present war; it will help us to understand neuroses and will prove that such really exist; that a symptom, though in a sense imaginary, may be in no sense non-existent. The term "shell-shock" is inexact but it is picturesque and connotative of the war. A discussion of its nomenclature elucidates the full significance of the term: both shell and shock refer not only to outward physical figures, but also to inward, functional or psychical meaning—the mechanical and moral, physical and psychical, traumatic and seismic, or as the French say *commotionnel* and *émotionnel*, aspects. Thus the ultimate physiological and psychological questions which confront the analyst of these conditions, whether termed shell-shock or more exactly war neuroses, are brought out. In the consideration of the relation between so-called shell-shock and the major groups of mental disease, the usual classification of mental diseases has been adopted at the Boston Psychopathic Hospital, where Professor Southard's observations for the most part have been made.

The principal groups therefore are: (1) *Syphilitic.* The solution of neurosyphilis problems will be vastly aided by the records of shell-shock during the present war, and this is particularly true of questions in relation to its course in time and its spinal and cerebral placement. (2) *Hypophrenic.* From the case history literature it would seem that the feebleminded, unless they be of that very high level sometimes called subnormal, are not particularly susceptible to the neuroses. It may be that the higher and more complex specimens of mankind are more susceptbile than the lower and more simple types. It is possible, moreover, that as a result of the war there may be a number of persons whose edges have been dulled by their experiences and who will constitute important problems in mental reconstruction after the war. Others may be voluntarily inadequate in some sense as a result of the military routine life, with its tendency to psychic sloth or even somatic laziness. (3) *Epileptic.* As far as the records of the National Hospital for the Paralyzed and Epileptic, London, goes, there does not appear to have been any increase in epilepsy on account of the war. Of course, any case of epilepsy returning from the front is regarded by his relatives as shell-shock. The relation between epilepsy and shell-shock, however, is not a close one. (4) *Alcoholic.* Though alcohol may complicate the issue, there is little or no direct relation here. (5) *Encephalopathic*, in the sense of some focal brain disease. Eliminating the forms already mentioned, including the syphilitic, nervous and mental cases, all give rise to the suspicion of organic disease, possibly traumatic in origin. Whereas in head injury the nerve phenomena will ordinarily be on the opposite side of the body, the reverse is true of hysterical cases. Many complicated cases, however, occur and a glance at the differential tables developed by the French neurologists will show how fine the diagnosis between a hysterical and an organic disease may be, especially when we consider the frequency of admixtures of the two. The rule holds for the vast majority of cases that bullet or shrapnel wounds do not prdouce shell-shock, and the statistical story is so clear that it might almost be thought that the wounds are in some sense protective against shell-shock, though not against traumatic or surgical shock. Each case should be given a complete neuropsychiatric examination, having due regard to Babinski's observation that such an examination gives opportunity for all sorts of mental suggestion to the patient. (6) *Symptomatic.* These cases present problems for the internist. The association of "D.A.H." and hyperthyroidism has been observed and a cure of the latter condition by hypnosis has been reported; this Southard points out may be possible in view of the still obscure relations between mind and hormones. (7) *Senile* or *presenile.* On the whole there is no special evidence that life is to be shortened or later years made more difficult by war experiences, unless there has been some specific disorder leading to incapacity in the war. The other groups are less well understood by the general profession. They are: (8) The *Schizophrenic*, commonly known as the dementia precox group. No great number of such cases have been produced by the war, a fact that would seem to indicate that the causes of dementia precox lodge more in the interior of the body, or in special individual reactions of the mind of the victim. (9) The *Cyclothymic*, sometimes called the manic-depressive group. It has not been found that such cases have developed during active service, the cases usually being in men who were cyclothymic before they entered the army. The lecturer observes that, with few exceptions, cases which fall into the last two mentioned groups should be unconditionally excluded from the army. The study of such conditions should be a part of every man's post-graduate training for both military and civilian practice. A tenth group consists of cases of psychoneuroses, which might be called *blooming* examples of hysteria. The difficulty, however, lies in diagnosing cases which are not such blooming examples. It is into this group that the majority of shell-shock cases fall. The great proposition deducible is therefore: *that the diagnostic problem in shell-shock is the diagnostic problem of neuropsychiatry at large.* Babinski has shown that beyond the psychopathic and neuropathic conditions, there is another kind of dynamic disease operating after the manner of Charcot's "reflex" disorders. In short, the dynamopathic or functional in nervous disease has been shown to fall into two parts—a psychopathic fraction and a non-psychopathic or physiopathic fraction or reflex. By chloroforming the patient Babinski was able to bring out certain reflexes or hypertonuses that in waking life were wholly concealed. The proof of a new type of functional disease was thus made plain and a new lead of the greatest value offered in the field of psychopathology—one step more in our knowledge of the Unconscious.

4. A Possible Factor of Degeneracy.—T. J. Downing suggests that racial degeneracy may be brought about through the mixture of peoples of different skull type. He points out that two well defined primitive skull types are coexistent with the earliest findings of man on the earth—the long and the broad headed types. The longitudinal diameter of the one is 100 and the transverse diameter less than 80, while the other has a longitudinal diameter of 100 and a transverse diameter of more than 80. The real variation is a long sella turcica and a broad sella turcica type. In these two types the harmony of structure and function, hived in and about the craniocerebral base, bespeak the most rigid and supercrystallized racial heredity and any departure in structure or in function necessarily results in a measure of disharmony. This is demonstrated by the relation subsisting between asymmetry of form, especially of head and face, and degeneracy, both of which may be due to disharmony of structure and function in and about the craniocerebral base. Broadly speaking, in a remote period of the past, the long heads occupied all Asia on this side of a line corresponding to the Western borders of China and India. Later they overran India. Of Europe they possessed the lands west of Central Russia; of Africa they occupied at least the valley of the Nile and the countries touching the Red Sea. Practically all other lands were in possession of the broad heads. Downing asserts that wars between peoples of the same skull type cannot be degenerative. In the present war we have at least three conserving factors looking toward efficient preservation and perpetuation of the race: superselection for the race when the women outnumber the men; eighty-five per cent. of our soldier boys will return after the war, racially and parentally nondebilitated, if not virgin; and the young men who remain at home have the same racial vigor and parental potentialities as the returning soldiers. War in itself is not degenerative, and a few generations will suffice for complete restoration. In this country a fourth conservative factor is woman suffrage. Chief among the good results will be a more complete segregation and a strong tendency against race mixing. On the other hand, wars between peoples of different skull types may be degenerative, depending solely on the degree of skull type mixing which follows. Friendly migrations would be equally disastrous. The writer further points out that it was not the wars that destroyed ancient civilizations, but the subsequent mixing of the people with neighbors of different skull type—the Egyptian with the African, the long heads of Asia Minor with the broad heads of Eastern Asia and Eastern Europe, the Spaniard with the African, and so on. Its accomplishment required centuries and its rebound, if any, will need other centuries of time. A happy medium of skull type may be evolved in the centuries to come and a fair level of mankind and civilization thus insured. The long heads who remain comparatively unmixed are the Celt, the Gael, the Teuton, and the Jew. In spite of the destruction of men, of wealth, of art, and of land in the present war, there is no cause for despair. Racial degeneracy and retrogradation will not result if there is no skull type mixing after peace is declared. Downing, however, senses danger in the idealism of universal democracy, world-wide socialism, etc. Should the long heads of Europe and America invite or permit immigration of the mixed and broad head skull types, centuries of retrogression will follow, and if there is a rebound—sometimes there is none—it will take other centuries for its accomplishment. It is possible, therefore, Downing thinks, that the problem of saving our civilization will be handed again to the Jews—whose very religion is to continue as an unmixed race—as it was for 3000 years after the wars of ancient Egypt, Asia Minor, and Middle Europe.

7. Rational Preoperative Treatment with Special Reference to Purgation.—Max Minor Peet argues in favor of simple enemas rather than preoperative catharsis. He points out that the experience of emergency surgery demonstrates that preoperative catharsis is not necessary, the patient standing the operation equally well without preparation and often enjoying a more satisfactory convalescence. He states, however, that there are cases in which the administration of a mild cathartic before operation may be of advantage, but such cases he considers the exception. The disadvantages of preoperative catharsis are: physical and psychic weakness; loss of sleep; loss of body and intestinal fluids; hypotonicity of the intestinal wall; change in the bacterial flora of the intestine, and irritability of the rectum and lower colon. The patient not subjected to this procedure is not as prone to suffer from thirst, nausea and vomiting, abdominal distension and gas pains.

1. The Goulsonian Lectures on Modern Views on Diabetes and on the Significance of Acidosis in Disease—Acidosis in Diabetes (Ketosis).—E. P. Poulton, in Lecture No. 2, refers to the work of various observers on the cause and significance of acidosis in diabetes and points out that the theory of neutrality regulation has now been generally adopted. This theory states that the reaction of the blood, or its hydrogen ion concentration, is preserved at a constant level by the organism, and means must be provided to compensate for any increase of acid or alkali in the body. There are three known methods of compensation. In the case of acid there is a lowering of the alveolar CO_2 by increased pulmonary ventilation, an increase in the production of ammonia which combines with the acid, and an increase in the hydrogen ion concentration of the urine. Evidence in support of this theory is found in the observations and experiments of Hasselbalch and Barcroft. The theory of acid-intoxication has formerly

been considered sufficient to explain death in diabetic coma. Poulton, however, believes that the acid substances aceto-acetic and β-oxybutyric acids are poisonous in diabetes and that aceto-acetic acid is the poison that causes coma. As was pointed out in the previous lecture (see MEDICAL RECORD, July 27, p. 163), this substance is produced by abnormal metabolism. The actual coma may be due to fall in blood pressure, the aceto-acetic acid acting primarily on the circulation. It is remarkable how invariably the consciousness of the patient varies with the strength of the pulse. A fall in intraocular tension is another well known indication of the onset of coma. Treatment should consist of fasting and underfeeding as described in the previous lecture, in order to lower the metabolism. Occasionally carbohydrates should be given, especially in acute cases due to faulty dieting. The administration of sodium bicarbonate, by mouth or intravenously, sometimes produces excellent results. Another point to be noted is that in long standing ketosis cases there is a draining of many inorganic substances from the body; it is therefore wise to give by mouth small daily doses of potash, soda, lime, and magnesia.

Berliner klinische Wochenschrift.

May 20, 1918.

The Treatment and Correction of Amputation Stumps.—H. Brütt believes that the cause of torpid evolution so common in amputation stumps, which does not end in good cicatrization, resides in insufficient blood supply in the flaps. The ulcers and fistulæ tending toward chronicity should be treated by massage and passive movements. Passive stasis has not given the results expected of it. Brütt develops the circulation in stumps by the use of a kind of dynamometer which transmits the muscular enlargement during contraction to a weight which is slowly raised and with an increasing facility as the treatment progresses. The quartz lamp and roentgenization favor elimination of the sequestra. Fetid ulcers are irrigated with Carrel-Dakin solution. The writer has seen some excellent stumps after Pirogoff's amputation and better for walking than those obtained by Chopart's method. At the knee Gritti's operation is preferable to amputation at the point of election, as well as to fixation of a prothesis on a flexed knee. When reamputation is required the writer prefers to cover the stump with a cutaneo-fatty flap. In opposition to many surgeons he forms this flap from the amputated limb itself, rather than from the normal fellow limb. A well performed plastic operation will give a good surface for the application of a prothesis.

Pernicious Staphylococcic Phlegmonous Enteritis of the Ileum.—A. Glaus describes a phlegmonous infection involving the latter portion of the ileum, and yet remaining clinically latent. The hypertrophic spleen contained the *Staphylococcus pyogenes aureus* in a pure culture. The writer supposes it to have an enterogenous origin.

Münchener medizinische Wochenschrift.

May 7, 1918.

Deep Antisepsis in Wounds of Warfare.—R. Klapp discusses "reinforced prophylaxis" that he advocated some time ago. It requires: (1) primary excision of wounds; (2) deep disinfection with solutions of quinine derivatives. Excision of the parts must be done as early as possible, and in some cases may be followed by primary sutures. By removing the necrotic tissues freely, likewise the bacteria already infesting them, excellent results have accrued to many surgeons. Infiltration of the cleansed wound is done with isolthylhydrosuprein, which is the quinic derivative having the greatest destructive action on the streptococcus and staphylococcus. Infiltration is obtained by means of a 1:10,000 solution of this product. Irrigations with the solution have not given such good results as the infiltration method advised by Klapp. This drug acts by slowly infiltrating in the dressings, which is equivalent to a drainage flow, by killing the bacteria and overcoming the leucocytosis and granulation tissue. The solution is made in a physiological salt solution, then filtered through cotton and sterilized. Novocain or suprarenal extract may be added if required. This procedure of infiltration should not be used in poorly vascularized flaps and the same may be said of the fingers. Bone lesions are to be freely exposed, cleansed with the chisel and evened off, and then all the splits in the bones are injected with the solution, which is also injected under the periosteum and surrounding tissue areas. Wounds of the joints should be freely incised down to the capsule, through which a needle is introduced and the joint injected with the solution. The aperture made by the needle is closed with a suture and after the extra articular wound has been infiltrated it is in turn sutured. Fixation of both bones and joints is absolutely necessary. Klapp next gives his results in various types of wounds. He advises secondary suture in the majority of cases, as it does not necessitate a renewal of the infiltration. Joint wounds have appeared to Klapp to be the most favorable for this procedure.

May 9, 1918.

The Treatment of Furunculosis and Carbuncle.—C. Schlatter passes in review the old and modern treatments of these cutaneous infective processes, which are so common among soldiers. Abortive treatment, with tincture of iodine, carbolic acid 10 per cent., ichthyol, or the thermocautery, is applicable at the beginning of the infection. All emollient treatment is to be avoided, as it renders the surrounding skin favorable for new foci of infection. Incision relieves the pain by diminishing the tension, but does not shorten the evolution of the process. Furunculoses in general are benefited by general care of the skin, such as washing with alcohol, with or without the addition of boracic acid, the application of a 10 per cent. formalin solution to the skin areas exposed to infection and desquamative applications, such as potash soap, or ointments of sulphur or naphthol. Radiations with the quartz lamp give good results. The autovaccines and polyvalent vaccines are now being studied. For carbuncle, local anesthesia being obtained, the focus is deeply incised and cleansed with the thermocautery.

Significance in the Diagnosis of Appendicitis.—E. Schlesinger admits that there can be a cecal stasis quite independent from appendicitis, ileostasis or constipation of cecal origin. This is proved by radiographic plates which show a permanent shadow over the cecal area which may be present for weeks, although the progression of the fecal mass onwards remains perfectly normal. This stasis is never due to a functional cause, but is generally attributable to peritoneal adhesions. Laxatives have little, if any, effect on it. Surgical interference, which is necessary when fecal retention is prolonged, should consist in mobilization of the colon by breaking up the existing adhesions and doing away with any recesses. Fecal stagnation of shorter duration (two to three days after the bismuth meal) can be treated by medical means. The writer offers several *x*-ray pictures of local diverticular stasis to back up his statements.

Wiener medizinische Wochenschrift.

May 25, 1918.

Galician Dysentery.—F. C. Krasa first refers to Popper's observations relating to an epidemic of dysentery observed in Galicia in which the etiological agent was not a bacillus but an ameba differing from any known organism at the time. Popper christened it "entamoeba dysenteriæ europeæ." The epidemic studied by Krasa occurred simultaneously with that observed by Popper and underwent its evolution in the same conditions. In spite of this, the Shiga-Kruse bacillus was found in most of the cases, the Flexner bacillus and the γ-bacillus less commonly. The exact proportions were: For 32 per cent. of cases having a positive bacteriology, 30.6 per cent. were Shiga-Kruse, 1.2 per cent. Flexner and 0.2 per cent. for the γ-bacillus. The writer explains the 68 per cent. of cases having a negative bacteriological result from the difficulty in cultivating the Shiga-Kruse organism, which is easily overgrown by

the bacterium coli if the sample of feces is not very fresh. Besides, the elimination of the bacilli in the feces may vary from one dejection to another and it may even happen that the bacilli present in the ulcerations are not eliminated in the stools at all.

Lactation and Malignant Tumors of the Female Breast.—Von Steiger refers to the belief that most women with cancer of the breast have undergone pregnancy and lactation and that the disease is deadlier when there has been repeated and prolonged nursing. This belief is by no means unanimous and claims have even been made that functional activity of the breast is a protection against malignancy. The author sought to test the subject in Swiss women, mostly from the canton of Berne. Ninety women with cancer of the breast had borne an average of 4.78. Thirty-four women with the same malady had never borne children. Of 74 women, two-thirds had nursed their children, and in about one-half of these lactation was normal. By abnormal lactation the author refers to premature weaning and drying up the breast. There were 14 histories of mastitis. The average age of the combined material was 52.5 years. Data on the duration of lactation are incomplete and the author was obliged to fix an arbitrary duration of five months or more, which he terms "normal." In any woman who did not nurse her infant five full months, nursing is set down as unphysiological. The only deduction of any significance is the relatively small percentage of cases of normal lactation as contrasted with the sum of the other cases. If of every four cases of cancer of the breast but one occurs in a woman whose breasts have performed their full physiological function, the latter can hardly be regarded as a predisposing cause. The author now obtained some control figures, as follows: He collected data concerning nearly 300 women whose ages averaged 50.3 years and whose children averaged 5.5 per woman. Of this number 76 per cent. had nursed their children, although only 28 per cent. had nursed over five months, as against 51 per cent. in the cancer material. These figures seem to invalidate the first ones, for they show that the per cent. of cancer cases with physiological nursing was almost double the average for that part of the country. For poverty or some other reason the women are evidently inhibited from protracted lactation and often from any lactation. If the combined figures prove anything at all, it is that on the whole lactation exerts an unfavorable influence and slightly predisposes to cancer.

Nine Cases of Tetanus with Recovery Under Magnesium Sulphate.—Janer has treated nine cases of tetanus in the past three years with the most satisfactory results. Of the nine cases five were acute, the symptoms supervening in from two to eight days after injury. Patient No. 1 was a boy of nine with a period of eight days' incubation who recovered under antitoxin and magnesium sulphate in not excessive dosage. The second case was in a man of sixty who required amputation of an injured finger. The incubation period was five days and recovery occurred under the same conditions of treatment. The third case was a boy of five, incubation period two days. The lesion was a nail wound in the foot. On account of the sudden supervention of the disease he was given antitoxin in larger dosage. As another medical man would not consent to the magnesium treatment, Baccelli's carbolic acid method was substituted, but as no improvement was visible the magnesium was given steadily for five days in very moderate doses; after this period the patient was seen to be out of danger. Patient No. 4 developed the disease after a fifteen-day incubation period. Serum is not mentioned in the treatment. Although the case is called mild, magnesium was given in full doses over a long period of time. Patient No. 5 was a young man without definite history of infection. He received no serum, but was given magnesium in high dosage—40 c.c. of a 50 per cent. solution for two days. The convulsions ceased after the second injection. Patient No. 6 was but seventeen days old, without evidence of umbilical infection. The author believed that death would be inevitable and gave magnesium merely as palliative. The mother and patient did not come back for treatment after the third day, but five months later the child was seen in good health. Patient No. 7 was a strong negro, aged 29, whose symptoms began only forty hours after having received a punctured wound. The entire picture of the disease, including opisthotonus, developed within a brief interval. The patient was given 9000 units of antitoxin and injections of magnesium were given three times daily. After six days the convulsions seemed under control. The offending object, a piece of umbrella rib, had not been completely removed and the patient was now submitted to an operation for this purpose, after which the magnesium apparently put a complete stop to further motor manifestations. Cases 8 and 9 presented nothing unusual and in both recovery occurred. The author naturally credits the brilliant outcome in this series of cases to the Meltzer treatment. The injections were all intramuscular.

Researches into Gas Gangrene of War Wounds.—Sacquépée has considered the edematous form of this affection in a prior article. Of other aspects he mentions first the gaseous toxic tumor in which there is swelling and elevation of the margin of the wound. There is an erysipeloid condition of the skin, phlyctens appear and the presence of gas may readily be made out in the tissues. The odor of the wound is sickening. There may be a profound systemic reaction, so that death may occur in 24 to 48 hours. This tumor type is an elemental one from which are derived several others. The gangrene may spread locally or septicemia may develop or the so-called bronze erysipelas may be the chief clinical manifestation. In this type of gas gangrene it is the muscles which suffer and the muscle lesions show the greatest degree and variety of behavior. There may be only a congested state with nothing to suggest gangrene, yet the bright red muscles may be infiltrated with air bubbles. The loose tissue about the muscles may be the seat of edema. The germ content comprises both aerobic and anaerobic organisms; among the latter the *perfringens*, septic vibrion, *B. bellonensis*, etc., and among the former the usual pyogenics. In hundreds of analyses made by the writer the germs most commonly found were the *perfringens* and staphylococcus, this being the commonest association. But one of two forms of the septic vibrion or the *B. bellonensis*, an anaerobe, is usually present, and considering these two anaerobes jointly one of them was present in 74 out of 100 cases. Despite some negative fruits the author believes them universally present at the outset, although perhaps not demonstrable later. To what germ or what symbrosis is the deadly character of the lesion due? The author tested the three leading suspects, *perfringens*, septic vibrion and *bellonensis*, in animal inoculation. The *perfringens* liquefies muscle tissue with formation of a putrid, sanious discharge and forms abundant gas in large bullæ and pockets. The septic vibrion causes a bright red color of the muscles with production of gas in fine bullæ. The *bellonensis* provoked extensive gas infiltration and an odor of gangrene. While the other two germs supplied powerful toxins, the *perfringens* appears to form no toxin whatever. An analysis of the phenomena resulting from inoculation appears to show that the septic vibrion and *bellonensis* are in a great majority of cases able unaided to cause the picture of gas gangrene in man. That the *perfringens* ever plays a major role in these cases is doubtful, but there is no reason to doubt that its pathogenicity is sometimes added to the activities of the others because of its presence in so many cases in large numbers. The author does not believe that the other germs, including the aerobics, play any considerable role. It is hardly conceivable that a great number of germs can engage in a pathogenic symbiosis. Such a view would make specific treatment impracticable.

Modern Urology in Original Contributions by American Authors. Edited by Hugh Cabot, M.D., F.A.C.S., Chief of the Genito-Urinary Department of the Massachusetts General Hospital; Assistant Professor of Genito-Urinary Surgery in the Harvard Medical School, Boston, Mass. Volume I. General Considerations. Diseases of Penis and Urethra. Diseases of Scrotum and Testicle. Diseases of Prostate and Seminal Vesicles. Illustrated with 368 Engravings and 7 Plates. Volume II. Diseases of the Bladder. Diseases of the Ureter. Diseases of the Kidney. Illustrated with 264 Engravings and 10 Plates. Price, $14.00. Philadelphia and New York: Lea & Febiger, 1918.

In the preface of this admirable work the editor writes apologetically that "All composite works have an inherent weakness in that they lack the smoothness and balance of works produced by a single author." He has, however, so limited his contributors and so logically arranged the sequence of their work that homogeneity is attained.

The introduction is a short history of urology in America and condensed biographic sketches of some of the more notable American urologists. There can be no debate on the wisdom of selection of these immortals and doubtless only lack of space prevented inclusion of other great men in the list. Chapter II deals with the cystoscope and its use. In these forty-nine pages the author, with consummate modesty, mentions his name only forty-nine times and that of his instrument maker only ten times. The third chapter, written by Bransford Lewis, entitled "Methods of Diagnosis in Lesions of the Urinary Tract," is especially commended, and his remarks on some vital truths regarding genito-urinary diagnosis are beyond compare in their content of sage advice to the practitioner. Section two, on diseases of the penis and urethra, is clear and instructive, and in accordance with the author's opinions and teachings as elsewhere expressed. The subject of urethral stricture is entrusted to Keyes, and the trust is well placed, since he covers the subject in concise and authoritative manner. But his pen never traced a more weird sentence than "The preventive treatment of stricture begins long before the stricture"; nor will Oberlander return thanks to him for designating him as "in Vienna." Neither will the followers of Guyon subscribe to this dictum: ". . . but unless the stricture is particularly complicated, or unless all followers have failed to pass, the tying in of a filiform is a waste of time." Nevertheless, these deviations do not detract from the excellence of the contribution. Section three, on diseases of the scrotum and testicle, is written by Smith, Stevens, Sanford, Barney, and Beer. These chapters are without exception clearly and concisely written. The illustrations of microscopic sections are intelligible inasmuch as the degree of magnification is indicated, which virtue does not obtain throughout the work. The volume ends with section four, devoted to the prostate and seminal vesicles, and written by Quinby, Pilcher, and Hugh Young. These contributions are of the high degree of excellence that might be expected of these authorities.

The section on the bladder in Vol. II is written by Kretschmer, Lower, Hagner, Caulk, Cabot, and Geraghty. Each contribution is thoroughly good, the best perhaps being those of Cabot on stone and foreign bodies in the bladder. These chapters may be accepted as models of conciseness and excellent presentations of the subjects. Hunner contributes all of section two, on the ureter. In these sixty-five pages he fully considers the anatomy, abnormalities, injuries, and diseases of the ureter. The essay is well written and replete with personal experiences. In his remarks on the anatomy of the ureter (page 253) he writes: "It is of practical importance to realize that the epithelial layers of kidney, ureter, and bladder are continuous and of similar composition, and that it is impossible in an examination of the urine to designate from which of these three organs the cells in the urine are derived. We still have patients bring written urinary analyses from laboratories where this differentiation is attempted, and it inevitably casts suspicion on the value of the entire report." This is an ill-advised attack on a method of diagnosis which has many followers and accepted by many urologists. Section three, on the kidney, is written by Quinby, Geraghty, Squier, Keyes, Edward L. Young, Jr., O'Neil, Cabot, and Binney. The anatomy and physiology of the kidney is of the usual text-book character; the description of tests of renal function is in accord with the authors' writings elsewhere published.

Chapter XI, on anomalies of the kidney, hydronephrosis, movable kidney, and injuries of the kidney, contains the only instance of overlapping or repetition in the work. The chapters on infections of the kidney and stone in the kidney and ureter are written by Keyes and Cabot. In the chapter on tuberculosis of the kidney and ureter, contributed by O'Neil, there appear twenty-seven pages of text on the pathology of this infection written by E. Granville Crabtree, to whom the editor gives no credit in his table of contents. The work ends with a chapter on tumors of the kidney by Binney, who holds to the accepted paths in all regards and liberally quotes Garceau's excellent work.

The index is good, the plates excellent, and in general the illustrations are well chosen and well executed. The reviewer is impressed (1) with the absence of repetitions and overlapping of subjects, (2) the thorough and careful review of worthy literature, (3) the completeness with which each subject is discussed, (4) the general clarity of expression, and (5) the perfect balance of subjects. In conclusion, the work may be placed in that Baconian classification of ". . . some few (books) to be read wholly, and with diligence and attention."

Cancer: Its Nature, Causes, Diagnosis and Treatment. By Robert Holmes Gréene, A.M., M.D., F.A.C.S., Emeritus Professor of Surgery, Medical Department of Fordham University, Etc. Price, $1.50. New York: James T. Dougherty, 1918.

In this book the subject of cancer is discussed under four headings: Causes of Cancer, Nature of Cancer, Diagnosis of Cancer, and Treatment of Cancer. In the preliminary remarks in the section on causes of cancer, Greene admits that we are as ignorant of the etiology of cancer now as we were when the study first began, and finds that none of the best known theories will stand all the tests. Apart from the realm of theory, the author has written in an interesting and instructive way on the nature, diagnosis, and treatment of cancer. These are the practical parts of the book, and will repay reading by every physician and surgeon. The author has emphasized many points that we think should be iterated and reiterated. For example, he says: "We cannot impress too strongly upon the physician and the patient the risk following undue handling of malignant tumors." And then, again, "Massage * * * should never be employed where the tumor is suspected of being cancerous and the examination of such growths should be undertaken with extreme gentleness and not repeated unless absolutely necessary." He also calls attention to the fact, well known to most of us outside the New York City Health Department, that cancer cells may be disseminated by incising a growth to obtain tissue for examination. In the section on diagnosis, considerable space is given to the technique of laboratory tests, especially for nonprotein sulphur in the blood and urine and the examination of gastric contents; while there are short but meaty chapters on differential diagnosis between epithelioma, syphilis, and skin diseases, on the *x*-ray and cystoscopic diagnosis, and other subjects.

Coming to the section on treatment, we find that the author believes that cancer is a constitutional disease and that operations for the cure of cancer "no more cure cancer, however much they may retard it, than does the removal of a tuberculous kidney cure tuberculosis; although both may be of help to the individual." He believes, however, that in proper cases the proper operative procedure will often retard its active development to such an extent that the individual's life may be prolonged for many years. Early diagnosis is essential for this happy operative result. According to the author, the basis of all successful treatment will be found in measures which tend to increase tissue metamorphosis.

SECTION ON PEDIATRICS.

Second Day—Friday, June 14.

Treatment of Prematurity.—Dr. ROOD TAYLOR of Rochester, Minn., presented this paper, in which he described the method employed in caring for premature children which was being used in the Pediatric Service of the University of Minnesota Hospital. From September, 1914, until the close of 1917 they had cared for 60 premature babies. The four-hour interval in feeding was employed. This they found prevented overfeeding, vomiting, and frequent disturbance of the baby. This interval between feedings had only one disadvantage, namely, it did not supply sufficient stimulation to the breasts and had to be supplemented by massage and pumping. The food was introduced by a small rubber catheter through the mouth. Only one baby in the series required tube feeding for two months, and only three as long as three weeks. The amount of food given was 100 calories per kilo body weight. The food required by a premature infant was about one-seventh the body weight daily. It was important that the baby's tolerance for food be not overstepped. The babies were clad in flannel hoods and capes, and 85° or 90° F. was the optimum temperature of the infants' beds. The bed temperatures were taken after the hot water bottles were removed. Fifteen of the babies that survived had a birth weight of less than 2 kilos and none of them weighed more than 2,000 grams. An antiseptic technique was employed, including the wearing of a mask by the nurse and by the mother when near the baby. It was important to avoid initial chilling. Only three of the babies required hospital care longer than two months. In premature babies rickets was frequent, and to prevent this disease at the end of the second month iron and cod liver oil were administered as a routine measure. Charts were presented showing the details in reference to feeding and gain in weight. Of the sixty babies, twenty-six survived.

Dr. JOHN ZAHORSKY of St. Louis said it was a much better practice to decide daily how much milk the baby should have, whether calculated by the caloric or percentage method. As to the interval of feeding, some babies did all right on the four-hour interval and others had to be fed oftener. The feeding was the most important factor in caring for a premature baby, and he made it a practice to try to work the energy quotient up to 120 or 130 by the tenth to the fourteenth day. He usually began the first day with an energy quotient of about 30 and then gradually worked it up. The interval between the feedings did not matter so much as that the baby got the proper amount of food. The cyanosis so frequently seen in premature babies was due to apnea and was largely dependent upon the amount of food. As to the temperature, it was necessary to begin with 85° or 90° F. and gradually decrease it. Slight overheating might produce cyanosis, because it decreased the child's power of oxidation and assimilation. He was especially interested in learning that they were no longer using incubators with their complicated machinery. For the apnea in premature infants caffeine and sometimes small quantities of tea might be given.

Dr. ISAAC ABT of Chicago said he supposed the four-hour interval between feedings would work out well in a considerable number of cases, but if they fed premature babies only every four hours they would have to feed larger quantities of milk than if fed at a two or three hour interval, and that would mean that the baby would be more likely to have the capacity of the stomach overtaxed and then it would vomit and lose part of the food. The point he wished to make was that they should not be bound by dogma, but should remember that they must always deal with babies as individuals. He believed that most premature infants would require feeding every two or three hours. Budin, in speaking of caring for premature infants, said that they suffered from two great troubles, the difficulty in controlling the body temperature and the difficulty in getting the infants to take sufficient food, and that it was better to feed small quantities at frequent intervals. The necessity of breast milk for premature infants should be emphasized.

Dr. LAWRENCE T. ROYSTER of Norfolk said that the vast majority of premature infants coming under his observation were in his private practice, outside of hospitals, and with these he had had some success. He imagined the stomachs of premature infants varied in capacity, just as did those of infants born at full term, and that therefore the quantity of milk would vary with different babies. He had not been successful in getting a four-hour interval unless he gave the milk through a tube, and he did not often use the tube because the mothers were not qualified to use it. His most frequent interval was two hours. Breast milk was almost a *sine qua non*, but sometimes one was driven to artificial food and when that occurred it was his plan to start feeding whey, diluted or whole, which would do to tide over a short period, and then he started cow's milk. Prematurity was a handicap and one met with a good many which were the result of accouchement forcé or cesarean section. It had been his experience that the premature babies delivered by cesarean section were easier to care for than those subjected to a tedious labor and a forceps operation.

Dr. FRANK C. NEFF of Kansas City, Mo., emphasized the importance of the antiseptic technique, and particularly of wearing a mask. Visitors should not be allowed about the premature baby. He had had no difficulty in teaching intelligent mothers to feed the babies by means of a tube.

Dr. JANE M. KETCHUM of Indianapolis said one very important point in caring for premature infants was that they should not be overhandled, and that furnished an argument in favor of the four-hour interval between feedings. She was using the tube for the first weeks. If the child was allowed to have a nipple in its mouth and make the effort to suck it learned sooner than if this were neglected. If a premature baby was low in fluids, a 5 per cent. glucose might be given per rectum and oxygen might be administered hypodermically for cyanosis. The baby should be weighed before and after nursing so that one would know what it was receiving.

Dr. JULES M. BRADY of St. Louis said he had heard Dr. Sedgwick read his paper advocating a four-hour interval between feedings at Atlantic City in 1910, and he was not convinced at that time that it was a good plan until he had tried it. If persistent vomiting occurred it was a serious symptom which diminished the infant's chances of living, and the four-hour interval lessened the possibility of vomiting.

Dr. B. B. ROWE of Duluth emphasized the importance of the face mask for those caring for premature infants. He said he had adopted the four-hour interval with the reservation that if he found it necessary he would shorten the interval.

Dr. H. M. MCCLANAHAN of Omaha spoke of the effect of the application of external heat, and cited an instance in which the temperature of the bed was 120° F. and the baby's temperature was 106° F. The baby died. In keeping up the temperature they had undoubtedly gone to the extreme in the past and certain infants were undoubtedly lost in the effort to conserve the body heat.

Dr. JAY I. DURAND of Seattle also emphasized the importance of getting the premature baby to take sufficient nourishment and disapproved the former custom of starving them on barley water. He had used the four hour interval and found that the younger the baby the more important it was to adhere to the four hour interval between feedings.

Dr. EDGAR J. HUENEKENS of Minneapolis said that to prevent rickets in the premature infant, basing his idea on the work of Schloss, he gave tricalcium phosphate with cod liver oil. The premature baby was not a normal baby and had to be guarded against anemia, spasmophilia and rickets.

Dr. HARRY LOWENBURG of Philadelphia said his experience was in accord with that of Dr. Abt, namely, that we must treat the individual. It was very dan-

gerous to become dogmatic. He had found it easier to pass the tube through the nose than through the mouth in these premature babies. One might give glucose solution through the anterior fontanelle. A propaganda should be carried to the obstetricians that they should either learn the principle of infant feeding or else leave premature infants alone.

Dr. WAHRER of Madison, Iowa, said it was well not to lose one's sense of proportion. They were making rules for the exception and rules for the exception to the exception. Some men sat up all night thinking about these things and they thought things that were only of their own thinking, but did not change the multiplication table.

Dr. ABRAHAM JACOBI said he had nothing worth while to add, but just to agree with what had just been said. In medicine, whether a thing made good or not, a doctor was always well off if he had brains and knew how to use them. He could not say that he approved of two, three or four hour feedings. They would have to use their brains in every case that came along. He thought the reader of the paper was correct in his own cases, but not in all others. One had to study the babies and the babies' mothers, so he could not say how long these babies could wait to be fed. Each baby needed to be seen by a doctor or a decent nurse and fortunately we had some decent nurses.

Dr. ROOD TAYLOR of Rochester said his paper was in no sense a propaganda for four hour feeding of premature babies. He had simply gone over Dr. Sedgwick's records of these babies and happened to find that they had been fed at four hour intervals. There was no doubt they must individualize. The four hour interval, however, helped to gauge the tolerance of the baby for the food. He had adopted this interval, but if he found the babies were not doing well he would change. All the mothers of these premature babies had been able to nurse their babies. He had had no difficulty in introducing the tube through the mouth and he thought that introduced in this way there was less danger of it entering the trachea and less danger of infection.

Intestinal Parasites in Children.—Dr. H. M. MCCLANAHAN of Omaha read this paper, in which he stated that the present classification of parasites was unscientific and he, therefore, presented the classification of Dr. Barber of Lincoln, Neb., and reviewed the recent literature. The tapeworm of meat and fish was rare in young children, but the tapeworm of the rat and the dog were more frequent and also more frequent than authorities recognized. Of the 100 cases in the series that were discovered in this paper the youngest child was five months and they were all under eight years. The tapeworm was about one-half inch long and was easily overlooked. Schloss in a series of 310 children under his treatment found intestinal parasites in 28 per cent., which would indicate that these parasites were not very rare. The fish tapeworm caused a peculiar weakness that was out of all proportion to other symptoms and was thought to be caused by a toxin of the worm. The symptoms of fish tapeworm were abdominal pain and mucus in the stools and sometimes disturbances were caused by the migration of the parasites. The writer had found on record twelve cases of intestinal obstruction caused by round worms. The diagnosis of thread worms could be made by inspection, though as a rule it was made by examination of the feces. Other things had been mistaken for worms or their ova, such as the fiber of fruits and vegetables or shreds of tissue of meats. Lay people are inclined to attribute everything to worms, while it had been the attitude of the physician to minimize their importance. The writer used the following procedure in making an examination for intestinal parasites. In the evening he gave a dose of santonin and calomel, followed the next morning by magnesium sulphate; or he might give fluid extract of epygelia. The stools were then kept for examination. He had used this routine procedure in fifty-seven cases. The plan of using the stomach tube to administer the medicine was a good one. It had been his experience that a great many of these cases were chronic in type and difficult to cure, and that might account for the many patent vermifuges on the market. In his experience it was often difficult to get the head of the parasite. Of 100 cases of dog tapeworm 34 per cent. occurred in sucklings one to six months of age and 42 per cent. in infants from seven months to three years.

Dr. WILLIAM WESTON of Columbia, S. C., said he had had experience in trying to eradicate uncinariasis which was quite unlike that of the British physicians in Egypt. He had found that there was a high birth rate and a low death rate among those infected with uncinariasis, but that their efficiency was markedly affected. He had tried all kinds of drugs for the eradication of these parasites and had found the oil of chenopodium most effective; it seldom failed when the cases were not complicated with other parasites.

Dr. LANGLEY PORTER of San Francisco said that the infection with threads was sometimes kept up by children scratching and getting the ova under their nails. As a protection against this they now packed the ends of the fingers with colodion. The medicine might be administered by having it put up into capsules and tossing the capsules into the pharynx. As an aid in getting the head, the child should be placed on a vessel full of water at body temperature, the water would support the weight of the worm, so that the other segments were not broken off from the head.

Dr. WAHRER of Fort Madison said that as a source of infection he would recall the old oaken bucket that hung in the southwestern corner of the well, in which rabbits, and sometimes rats, rested for a while, and the old mother was probably right in saying that the child had worms when it was pale and nervous and ground its teeth at night. She then gave three or four tablespoonfuls of turpentine. Mothers should be warned that this remedy was extremely dangerous, and also that there might be danger in the patent medicines containing santonin. He cited one instance in which the mother thought the child had worms, but investigation showed banana fiber; the child had eaten seven bananas the day before. He had also had several cases of myiasis come under his observation.

Dr. ROOD TAYLOR of Rochester cited an instance of lamblia infection in a child in which the mother had been treated for lamblia intestinalis. This parasite infected the upper small intestine and it was very difficult to get drugs in contact with this locality.

Dr. MCCLANAHAN, in closing, said there was one point that he left out. One frequently found intestinal parasites during acute infections where they had not been suspected, and he wondered if the worms were not partly responsible for the infection. He had used a mercurial salve for thread worms which he thought was effective. The *Lamblia flagellata*, he believed, was now considered pathogenic.

Purpura Abdominalis in Early Life.—Dr. WILLIAM WESTON of Columbia, S. C., presented this paper, the object of which, he said, was to call attention to an extremely interesting symptom complex which had received scant attention. A number of cases of purpura abdominalis had come under his attention during the last four or five years and three of these cases presented very interesting features, which were discussed in connection with the report of three illustrative cases. The outstanding symptoms in these cases were loss of appetite, irritability, thirst, abdominal crisis, sometimes severe pains about the joints, and skin manifestations of a wide variety. The pain was most often located in the epigastric region. The pulse was small and frequent, and in the writer's cases the pupils were widely dilated. In no case was there redness about the joints. Fever was present in all the cases and toward the end of the attack the temperature fell to below normal. The leucocytosis was from 18 500 to 28,500. The blood pressure was normal. Albumin was present in the urine in two of the three cases and the most frequent complication was acute nephritis. Angioneurotic edema was present often enough to be considered to have a definite relation to the condition. In the treatment rabbit and sheep serum was to be preferred to horse serum, but human serum gave the best assurance of permanent relief.

Dr. J. A. FOOTE of Washington, D. C., said that the question of the etiology of the purpuras was so involved that one could not say that much progress had been made in its solution. There was a similarity of these diseases to the diseases due to vitamine deficiency, and it was possible that there might be a factor of infection complicating the whole matter. One case of purpura

abdominalis had come under his observation in which the classical symptoms of appendicitis were present and the boy was sent to the hospital for operation. He was found to have a subperitoneal extravasation near the sigmoid. The boy recovered and the surgeon did not have any particular trouble with hemorrhage during the operation. The relationship of the purpuras to infection was suggested by their occurrence after measles in some cases. One could not be certain that it was due to a food deficiency or entirely to an infectious condition.

Dr. Rood Taylor of Rochester, Minn., said he had seen a number of these cases and found that the factors entering into the etiology differed greatly in the individual cases. There had been an attempt on the part of the physiologists to put the purpuras on a basis similar to the hemophilias, and they had also been attributed to a deficiency of blood platelets. He had had occasion to go through the records of the cases at the May clinic and found that in many there was evidence of some serious focus of infection, and all that were treated by removal of the focus improved greatly. Frequently the focus of infection was in the tonsils or teeth. Most of the cases did not have a low blood platelet count; the count was usually around 100,000. They had not been able to check the hemorrhage by transfusion anything like as easily in the purpuras as in hemophilia.

Dr. Isaac Abt of Chicago expressed the belief that the types of purpura found in children were different from those seen in adults. He asked Dr. Weston what his results were from the use of adrenalin.

Dr. Turner of Des Moines, Iowa, cited two cases belonging to this class, in one of which there was complete paralysis of the left arm and leg and of the right face, and the child died. In the second case, which was treated with calcium lactate, epilepsy developed, probably the result of hemorrhage in the brain.

Dr. Weston of Columbia, S. C., in closing, said he was glad to hear one of the men who discussed the paper say he had met a case of this condition in a negro, as this was something he had been looking for but had not thus far seen. In regard to the focal infections in early childhood as a cause of purpura, he had been unable to find any such focus in his cases. He had used adrenalin in one case, but got absolutely no results. His object in presenting the paper was to call attention to the possibility of confusing this condition with intestinal indigestion, with appendicitis, and with intussusception.

Hemophilia.—Dr. Harry Lowenburg and A. I. Rubenstone of Philadelphia presented this paper, reporting a case with complete experimental data bearing on the effect of glycerized extracts of visceral hemophylic tissues on the coagulation time of blood from healthy individuals. The tissues were obtained from a case showing remarkably slow coagulation time of the blood which came into the pediatric service of the Mount Sinai Hospital of Philadelphia. This boy bled to the extent that the slightest pressure produced ecchymosis. Two maternal uncles and a brother were also hemophiliacs. In making his experiments he had used Howland's oxylate and calcium chloride method. Tissue extracts from various organs of the body of this hemophiliac were tested against normal bloods, with the finding that the coagulation time was lengthened slightly by the cell of the tissue extracts, but most markedly so by those of the liver and thyroid. These experiments suggested that the liver and thyroid secreted an antithrombic substance which prolonged the coagulation time of the blood.

Dr. William Weston of Columbia, S. C., suggested that in the treatment of hemophilia it might be well to keep in mind the fact that the lack of fresh food might have some influence on the condition.

Etiology and Treatment of Enuresis.—Dr. Joseph Grover of Boston read this paper, in which he said that enuresis had many causes, among these two important ones were run down physical condition, due to poor food and irregular habits, and pin-worms. A large proportion of these cases could be cured within twenty-four hours, and many others could be cured or greatly relieved by strict care of the diet, sleeping and resting hours. In many instances the habit was due to an underlying neuromuscular fatigue, which affected the nerve center controlling the genitourinary mechanism, which resulted in a condition somewhat similar to a tic or habit spasm. This was taken care of by regular intervals of micturition and by allowing a limited amount of fluid toward evening. A series of 200 cases were analyzed, in which tonsils and adenoids, adherent prepuce and clitoris, and high urinary acidity were not considered or treated as causes for the disease. Accompanying nervous diseases usually disappeared with the bed-wetting. As rest was of great importance in these cases, an initial period of three or four days in bed had often proved of great benefit. In this series of 200 cases 62 per cent. were boys, and there was a predominance of blonds. In 69 per cent. the enuresis was only at night, in 38 per cent. in the daytime and night. In 68 per cent. the wetting occurred every night. Enuresis was probably never a disease entity. The psychical element was often a prominent factor in the control of the disease.

Dr. H. M. McClanahan of Omaha said he had never seen enuresis helped by circumcision. In children from six to twelve years of age many had enuresis because the viscus was small. Such children he had a confidential talk with and persuaded them to try to go a little longer without urinating in order to develop the size of the bladder, and he also advised them to stop two or three times during micturition as this helped the child to develop control of the musculature of the genitourinary mechanism. Another point was that the bladder should be thoroughly emptied at each micturition and very little fluid should be given at night.

Dr. M. L. Turner of Des Moines, Iowa, said his experience was a little different from that of Dr. Grover. He had read some place that enuresis was due to a lack of development of the nerve center controlling the bladder, and that if one would impress it on the mind of the child that he must control the bladder sphincter he could be cured of enuresis in twenty-four hours. He believed this was true in 75 per cent. of the cases. One point upon which he insisted was that no fluid should be taken after 4 P.M., and if the mother would impress on the mind of the child the fact that this restriction was for the purpose of controlling the bed-wetting, it frequently resulted in the child stopping the bad habit. Another measure he employed was prescribing the bitterest medicine he could concoct and having the child take three or four doses late in the day, at the same time impressing on his mind that the medicine was administered to stop the wetting. He believed one got better results by working along psychical lines.

Dr. Franklin N. Rogers of Manchester, N. H., emphasized the importance of rest as a factor in the treatment of enuresis. He said there was a tendency to shorten the hours of rest for children in consequence of the daylight saving plan. It was now difficult to get children to go to bed at 7 P.M.

Dr. Grover, in closing, said he agreed that in many cases a cure could be effected by psychical treatment and he cited several such instances, but there was a certain percentage of cases that were dependent upon the general condition of the child, and for these diet and rest were important factors in the treatment.

Dr. Harry Lowenburg of Philadelphia said he had come prepared to discuss Dr. Louis Fischer's paper on "Transfusion Through the Longitudinal Sinus" and regretted that the paper was not read, as he had three cases of hemophilia treated successfully by transfusion into the longitudinal sinus which he wished to report. The blood counts made before and after transfusion showed a marked increase in red cells and the hemoglobin percentage. The counts, which were very low before transfusion, approached the normal afterward.

Further Use of Pertussis Vaccine Controlled by the Complement Fixation Test.—Dr. E. J. Huenekens of Minneapolis presented this communication. After reviewing the preliminary report on his work along these lines, presented before the New York meeting of the A. M. A. in 1917, he said that in the experiments now reported he had used pertussis vaccine from two to three months old, employed in very large doses. One billion and over of dead bacilli immunized in 12½ per cent. of cases. Two to four weeks old vaccine conferred immunity in from 25 to 75 per cent. of cases. Freshly prepared vaccine, employed in the same dosage, showed evidence of antibody formation in 94 per cent. of cases.

When used in still larger doses, one, one and one-half, and two billion bacteria, 100 per cent. positive reactions were obtained. The antibodies were demonstrable within one week after the last injection. The following conclusions therefore seemed warranted: Pertussis vaccine should be employed only when freshly prepared and without preservative. By fresh vaccine was meant a vaccine less than one week old. The most effective dosage was one billion, one and one-half, and two billion, given on alternate days for three doses. It was most effective as a prophylactic, but should be of great value in the early catarrhal stage of pertussis. In doubtful cases of pertussis the vaccine should be administered before an exact diagnosis could be made, especially during an epidemic or where there was a history of previous exposure.

Dr. James T. Christison of St. Paul said that, speaking from the clinical side, they had had a very marked epidemic of whooping cough and had used vaccines in 100 cases with most astounding results. Since the beginning of the use of this particular vaccine the results had been so astonishing that they could hardly believe them possible themselves. In the State Hospital they had never gone through a winter without an epidemic of whooping cough, but this last winter they had not had a single case in the whole house, where they were caring for 165 children. He made a plea that the vaccines for pertussis prepared as described in this paper be investigated. Some children who had been exposed to the disease and in whom the catarrhal symptoms had developed were given the first dose of vaccine at this time, and the disease was apparently aborted. The highest number of injections given for immunization during the catarrhal stage was six. In families in which there was already one case of whooping cough the vaccines were given to other children in the family who had been exposed to the disease, and no secondary case had developed.

Dr. John Zahorsky of St. Louis said he had always felt that children only became immunized after a period of time, that we could not expect to immunize them with one large injection, and that it was better to give more than one injection. Bordet had called attention to the importance of the time element. It was his custom to give a good many injections over several weeks.

Dr. J. I. Durand of Seattle said that two years ago he was working with the pertussis vaccines of the New York Health Department and was very much impressed by their prophylactic value. He had since used commercial vaccines which had not given as good results.

Dr. E. C. Fleischner of San Francisco spoke of the autolysis of vaccines. The dead tubercle bacillus injected intraperitoneally into guinea pigs caused marked lesions in the omentum. At the end of two months lesions were found but the disease did not become generalized and they could not get cultures containing the bacilli from the lesions. The material from the lesions, however, gave a positive complement fixation reaction using the tubercle bacilli as an antigen, and yet two or three months after the injection there was no evidence of antigenetic properties in the lesion. On post mortem examination no tubercle bacilli were found in the lesions which would indicate that autolysis had taken place. The possibility of the autolysis of vaccines should be taken into consideration.

Dr. Frank C. Neff of Kansas City said that hitherto the results obtained from the pertussis vaccines had been so variable that no conclusion as to their value could be reached; Dr. Huenekens had shown that definite results might be obtained. It would be interesting to see how long this immunity lasted. It was well known that some individuals had a second and even a third attack of whooping cough, and this might indicate that artificially produced immunity might not be permanent.

Dr. J. A. Foote of Washington, D. C., asked Dr. Huenekens if he had come to any conclusion as to the exact time it required to produce the complement fixation reaction after the vaccines had been administered. He asked this because it was important in connection with the use of the vaccines in the treatment of whooping cough.

Dr. Cass of Milwaukee made the point that, in connection with the cases supposed to be recurrences of whooping cough, it was well to remember that other microorganisms besides the Bordet-Gengou could produce the symptoms of whooping cough, as for instance the *Micrococcus catarrhalis*.

Dr. Huenekens of Minneapolis said he had omitted many points in reference to the clinical side of the subject and had presented only the laboratory facts. A positive complement fixation test did not necessarily mean that immunity to whooping cough had been produced; it meant that antibodies were being produced, but possibly they might not be sufficient in quantity to produce immunity. All did not give a positive complement fixation after one dose of vaccine, no matter how large a dose was given; hence, time might be a factor in the production of immunity. With reference to administering the vaccines over a long period of time, his object from the clinical standpoint was to make the administration of the vaccines as simple as possible, consistent with the production of immunity. He thought the difference in results that had been reported from the use of pertussis vaccines was probably due to changes that had taken place in the various vaccines employed. He thought he could find the effect of vaccines of living bacilli on animals but found that they gave positive complement fixation tests before they had received the pertussis vaccines.

Cutaneous Hypersensitiveness as an Evidence of Infection, and Its Bearing on the Pathogenicity for Infants of the Bacillus Abortus Bovinus.—Dr. Emanuel C. Fleischner and Dr. K. F. Meyer of San Francisco presented this communication, which was read by Dr. Fleischner. He recalled that in 1916 and 1917, with the view of ascertaining the frequency of tubercle bacilli in milk, they had injected a large number of guinea pigs, and as a result found that the animals did not develop tuberculosis but developed the symptoms indicative of infection with the *Bacillus abortus*. The conclusion drawn from that investigation was that the certified milk examined was a perfectly safe food so far as tuberculosis was concerned. As a result of the injections with the certified milk the guinea pigs developed a skin reaction characterized by induration and an areola with usually a central necrosis. This reaction lasted over forty-eight hours. They had since conducted a series of experiments in an effort to determine the value of cutaneous hypersensitiveness as an evidence of infection, in the course of which a large number of animals were inoculated with the *Bacillus abortus bovinus*, and in practically every instance positive skin tests were obtained. Negative skin tests, on the other hand, were the universal result in animals that had been inoculated with dead abortus bacilli and with abortion. Realizing that in the consumption of raw milk a large number of abortus bacilli were ingested, intradermal tests were made on a series of infants to determine the possible pathogenicity of this organism, following the same technique that had been employed in the case of experimental animals. In a series of 75 infants receiving injections of milk rich in abortus bacilli cutaneous hypersensitiveness was not manifested in any instance; from this it was concluded that the *Bacillus abortus bovinus* was not pathogenic for infants.

The Remote Results of Tonsillectomy in Young Children.—Dr. John Zahorsky of St. Louis read this paper, which was based on the study of 150 children. He stated that the removal of the tonsils was often followed by immediate good results. The children might improve so far as their appetite was concerned and might feel better and gain in weight, but in judging of the results of tonsillectomy sufficient study had not been given to the remote results. The children in this series were from his private practice and ranged in age from two to twelve years. Among these children he found, subsequent to operation on the tonsils, rhinitis in 38 instances, otitis in 21, bronchitis in 49, pneumonia in 43, asthma in 16, rheumatism in 9, endocarditis in 7, chorea in 6, adenopathy in 15, and diphtheria in 3. There was manifested among these children an increased tendency to bronchitis, bronchial pneumonia, and malnutrition. One could not depend upon tonsillectomy to improve the general condition of a child. It was much better to direct attention to the development of immunity and of a vigorous resistance to disease than to rely upon tonsillectomy to eradicate infec-

tion. A child must have one or more attacks of a disease in order to develop immunity. This was probably the reason gastrointestinal disturbances were so frequent in infancy; they were an indication of an attempt to produce immunity to intestinal microorganisms of different varieties. It was also notable that during the first two years a child attended school he, as a rule, suffered from a series of colds and respiratory affections and then seemed to become immune to them to a certain extent. He wished to make it emphatic that in children under eight years of age one should only remove the tonsils after a careful investigation of the nutrition and resistance of the child by a pediatrist; he was the one to decide whether the tonsils were to come out or not. He also wished to protest against the tendency to attribute everything from chorea to appendicitis to diseased tonsils. With the incomplete removal of the tonsils before the age of seven years, there was a tendency for the lymphoid tissue to return. When a child had an acute infection of the tonsils or a tonsillitis the present tendency was to operate immediately. In these cases it might be better to wait until the acute infection had subsided.

Dr. Harry Lowenburg of Philadelphia said that Dr. Zahorsky had brought up a most important subject and had made one statement with which they would all agree, namely, that the question as to whether the tonsils should be removed should be decided by the pediatrist. His experience, however, was not at all in accord with that of Dr. Zahorsky in regard to the other statements that he had made. He felt convinced that the pediatrist, in the interest of child conservation, was in need of propaganda to have the tonsils removed more frequently than was being done. This propaganda should be popularized. In the hands of a good operator it was better to take out healthy tonsils rather than to err on the other side by leaving in diseased tonsils. He hoped that it would not go out from this section that the consensus of opinion of the section was against tonsillectomy. He hoped the child conservation propaganda would include the advice to have the tonsils removed more frequently. Any one who had observed cases of rheumatism and endocarditis before and after the removal of the tonsils could not disregard the tonsil as an etiological factor in these diseases. Dr. Zahorsky's statement that a child had to have one or more attacks of an infection in order to become immunized to it did not appeal to him. He was very sure that one attack of heart disease should lead one to decide to remove the tonsils. An attack of acute follicular tonsillitis was also an indication for the removal of the tonsils just as much as an attack of acute appendicitis was an indication for the removal of the appendix.

Dr. Isaac Abt of Chicago said that he was surprised that Dr. Zahorsky held such views. The fact that a few cases of subsequent tonsillectomy developed various diseases did not prove the point he attempted to make. The idea that a child should be sick a great deal in order to be well a little was not in accord with the teachings of physiology, pathology, or biology. Dr. Zahorsky's contentions were fallacious.

Dr. E. C. Fleischner of San Francisco also deplored Dr. Zahorsky's attitude on this subject, and said that the laity had come to recognize the value of tonsillectomy and that if the health of children was not improved by this operation they would have found it out and would not permit their children to be operated upon. The beneficial results of tonsillectomy properly performed were well recognized by the lay public. It was a great mistake to make statements such as those of Dr. Zahorsky, because many men in the profession might believe them and they might work a great deal of harm. The teaching should be that tonsillectomy in properly selected cases and by properly selected operators provided a means of improving the health of many children.

Dr. Langley Porter of San Francisco said he thought Dr. Zahorsky in reality did not think any differently than the rest of them did in regard to tonsillectomy. The whole thing resolved itself into the question of whether the tonsil had any function in the body, and nobody was able to demonstrate that unequivocally. Even if a normal tonsil had a definite function, when it became infected it was no longer fitted to perform that function, and hence the individual having infected tonsils was as well off, or better off, without them than with them. A focus of infection in a tonsil should be drained just as would be done in any other part of the body, and that meant removal of the tonsil. In reference to the mouth breathing after tonsillectomy or adenectomy, attention had been called to the fact that where there was a high palatal arch the removal of the tonsils and adenoids might not correct the mouth breathing; in such cases the services of an orthodontist were needed.

Dr. Zahorsky, in closing, said that he still felt that the removal of the tonsils was done too carelessly in many instances, and that the teaching that the tonsil was a menace to the human body, and that wherever one was able to see a tonsil it should come out, was all wrong. He was not talking about abscesses, imbedded tonsils, or of obstructions that prevented breathing, but he was protesting against the idea that the removal of the tonsils would cure everything. With reference to the question of having an infection and thus producing immunity, he felt sure that a pneumococcus otitis had prevented many from having an attack of pneumonia.

Group Medicine and Pediatrics.—Dr. Charles E. Hansel read this paper, in which he emphasized the need for pediatricians in the smaller cities and described the difficulties encountered in establishing such a specialty outside of the large centers. He believed that group medicine would aid in the solution of this problem and that this would react to the welfare of the public, and especially to that large class of people who were not able to employ a specialist and who did not wish to accept medical treatment as a charity. One reason for the failure of group medicine was that sometimes one man wished to occupy the center of the horizon and the rest were only satellites. Every man in the group should be willing to consider himself but a cog in the wheel, and should be willing to sacrifice something and to cooperate with the others in the group. The problem of adjusting finances had often proven a stumbling block to group medicine. He suggested a plan whereby each man in the group should receive a sum equivalent to the income he had been receiving from his practice during the preceding one or two years, and the excess profits should be pooled and distributed in such a way that the incomes of the various members would tend to become equalized. A group should not include more than six or seven men or it would become unwieldy. Group medicine offered a number of advantages, one being that the mediocre man could do better in a group than alone, because he could devote all his time and energy to one field.

Dr. R. N. Andrews of Mankato, Minn., said he had belonged to a group for two years and would not go back to the old way of practising medicine. The question of finances was an important one and had to be adjusted satisfactorily if the group was to be successful. In the group to which he belonged the surgeon and the internist received equal incomes.

Dr. F. N. Rogers of Manchester, N. H., described his experience with group medicine and said he considered group medicine a failure and merely another method of fee splitting.

Dr. Joseph I. Grover of Boston said he had once been asked to join a group in a Massachusetts town and had investigated the matter and found that the other physicians in the town did not seem to feel very kindly toward those belonging to the group, and he had decided that a man would do better to keep out of such a group.

Dr. O. W. Rowe of Duluth spoke of the advantages of this plan and said one got swifter action through a group than by the old way. He acknowledged that physicians outside of the group were apt to hold aloof from those associated with the group.

Dr. Hansel, in closing, said that while the other physicians might stand aloof at first, that stage would be passed after a time. He had gone through the experience and knew whereof he spoke.

The Diagnostic Study of Conditions in the Throat Producing Dyspnea.—Dr. Albert Bell of Cincinnati said that there were two types of dyspnea, one type in which the breathing was of increased frequency and another in which it was slow with increased depth. He described the mechanism of these types and reported the case of a child supposed to have laryngeal diph-

theria when brought to the hospital. The child was suffering from dyspnea and difficulty in swallowing. When brought to the hospital the child's temperature was 100°, pulse 139, and the respirations were slow and deep. The diagnosis of laryngeal diphtheria was questioned because the child did not have the constant rhythmical distress that was characteristic of the laryngeal stenosis of diphtheria. The author then described the symptoms and signs of foreign bodies, adenitis, laryngeal diphtheria, retropharyngeal abscess, thymus enlargement, etc., and compared them with the findings in the case reported. The decision reached was that in the case reported the diagnosis was retropharyngeal abscess.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

December, 1917.

(*Continued from page* 134.)

MATERIA MEDICA.

1. Tartar emetic; name the official preparation and give the dose as an expectorant and as an emetic, and the incompatibles.

2. (*a*) Name six official preparations of mercury. (*b*) Name two alkaloids of opium.

3. (*a*) Give the official name and dose of Epsom salts, Rochelle salts, and Glauber's salts. (*b*) State strength of dilute hydrochloric acid as compared to absolute acid.

4. What is incompatibility in medicines, and what are the different kinds of incompatibles? Give examples of each.

5. How does an antagonist differ from an antidote? Give examples.

6. (*a*) Define briefly electricity as a remedial agent. (*b*) Define massage.

7. (*a*) Name the official preparations of zinc. (*b*) Mention the alkaloids of nux vomica.

8. Name a vesicant derived from the animal kingdom, one derived from the vegetable kingdom, and one from the mineral kingdom.

9. (*a*) Define antiseptics. (*b*) Name two intestinal antiseptics most generally used. (*c*) Name three most generally used externally.

10. Define toxins and antitoxins, and mention some conditions in which serum therapy has proven successful.

THERAPEUTICS.

1. Name four salts of sodium, and special uses.

2. Write two prescriptions in official terms, without abbreviations, containing three ingredients; one prescription for use as a stomachic, the other for acute rheumatism.

3. Therapy of nux vomica—preferable preparations, and mode of administration.

4. Acidum tannicum—therapy and preferable preparations.

5. Emetinæ hydrochloridum—therapy and administration.

6. Epinephrina—therapy and administration.

7. Paraffinum—therapy and method of use.

8. Therapy of hydg. bichlor. and hydg. chlor. mite.

9. Three salts of ammonium—therapy of each.

10. Therapy of belladonna—symptoms of overdose and treatment.

PATHOLOGY.

Give pathology of:

1. Acne vulgaris.
2. Acute otitis media.
3. Pernicious anemia.
4. Angina pectoris.
5. Locomotor ataxia.
6. Tuberculus meningitis.
7. Acute nephritis.
8. Dental caries.
9. Reynaud's disease.
10. Duodenal ulcer.

ANSWERS.

MATERIA MEDICA.

1. The *official name* of *tartar emetic* is Antimonii et potassii tartras. *Dose*, as an *expectorant*, 1/12 grain; as an emetic, ½ grain. *Incompatibles* are: Acacia, mineral acids, alcohol, alkalies, ammonia, ammonium carbonate, antipyrine, carbonates, bicarbonates, calcium chloride, gelatin, lead salts, lime water, mercuric chloride, metallic salts, sulphides, tannic acid and vegetable astringents.

2. *Six official preparations of mercury.*—Hydrargyri chloridum corrosivum, hydrargyri chloridum mite, hydrargyri iodidum flavum, hydrargyri iodidum rubrum, hydrargyri oxidum flavum, hydrargyri salicylas.

Two alkaloids of opium: Morphine, codeine.

3. *Epsom salt* is Magnesii sulphas, *dose*, four drachms; *Rochelle salt* is Potassii et sodii tartras, *dose*, two and a half drachms; *Glauber's salt* is Sodii sulphas, *dose*, four drachms.

Hydrochloric acid contains 32 per cent. of HCl.

The dilute acid contains 10 per cent. HCl.

4. *Incompatibility* is that relation between medicines which renders their admixture unsuitable. Incompatibility may be chemical, pharmaceutical, or therapeutic. *Chemical incompatibility* is seen in compounding an acid with a base, and forming a salt. *Pharmaceutical incompatibility* is seen in compounding a resinous tincture with an aqueous solution. *Therapeutic incompatibility* is seen when two agents are administered together which have an opposite action, such as belladonna and physostigma.

5. *Antidotes* are remedies which, acting chemically, physiologically, or even mechanically, are capable of combatting and neutralizing the effect of poisons on the system. *Examples*, alkalies and dilute acids; magnesium sulphate and lead salts.

Antagonists are medicines which possess exactly opposite properties to each other. *Example*, atropine and morphine in their action on the pupil of the eye.

6. "*Electricity* is employed in medicine to restore functional activity to peripheral nerves and muscles when conduction has not been completely cut off by some irreparable lesion; to promote general nutrition; to arouse the nerve-centers in states of depression; to combat various sensory disturbances which are of a functional character or which depend upon minor lesions of the peripheral nerves or their centers; to effect the rapid passage of drugs through the unbroken skin (cataphoresis); to bring about the coagulation of blood in aneurysmal sacs; to favor the absorption of inflammatory or degenerative products; and in the form of the galvanocautery, to excise or destroy hypertrophied tissues or morbid growths."—(Stevens' *Modern Materia Medica.*)

Massage is a method of systematically rubbing, kneading, or stroking the body for the (supposed) purpose of breaking down adhesions, modifying nutrition, or improving the circulation.

7. The *official preparations of zinc* are: Zinci acetas, zinci carbonas præcipitatus, zinci chloridum, zinci oxidum, zinci phenolsulphonas, zinci stearas, zinci sulphas, zinci valeras, and zincum.

The *alkaloids of nux vomica* are: Strychnine and brucine.

8. *A vesicant derived from the animal kingdom*, cantharides; one derived from the *vegetable* kingdom, mustard; one derived from the *mineral* kingdom, iodine.

9. *Antiseptics* are agents that prevent or hinder the growth of microorganisms, without necessarily destroying them. Two *intestinal antiseptics:* creosote and guaiacol. Three *external antiseptics:* potassium permanganate, mercuric chloride, and iodine.

10. *Toxins* are poisonous products of bacteria.

Antitoxins are substances manufactured in the body, which neutralize the effect of toxins.

Serum therapy has proven successful in plague, rabies, diphtheria, tetanus, typhoid, streptococcus infection, serpent venom, and other infections.

THERAPEUTICS.

1. *Sodium bicarbonate* is an antacid, and gastric sedative; it is also an analgesic.

Sodium carbonate is an antipruritic.

Sodium sulphate is a purgative, and hepatic stimulant.

Sodium chlorate is a deodorant, detergent for ulcerated surfaces and foul sinuses; it is also used in tonsillitis and laryngitis in the same way as potassium chlorate.

2. *As a stomachic:*

℞ Sodii bicarbonatis.....ʒij
Tincturæ zingiberis.....ʒiv
Infusi gentianæ compositi (U. S. P., 1870), q. s., ad.....ʒviij
Misce et signa: One tablespoonful before meals.

For acute rheumatism:

℞ Sodii salicylatis.....ʒiv
Potassii bicarbonatis.....ʒiv
Aquæ menthæ piperitæ, q. s., ad.....ʒiv
Misce et signa: One dessertspoonful, in water, after each meal.

3. NUX VOMICA. *Preferable preparations:* Tincture, dose ɱv-xx. Strychnine sulphate, dose gr. 1/60 to 1/30. The tincture may be given in fluid form; the strychnine in pills or tablets. *Physiological action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes. *Therapeutic indications:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

4. TANNIC ACID. *Therapeutics:* "Locally, tannic acid is much used to check excessive secretion and to impart tone to relaxed mucous membranes. In subacute and chronic laryngitis and pharyngitis a solution of from 1–5 gr. to the ounce makes a useful spray. Some surgeons have found injections of the glycerite, more or less diluted, efficacious in subacute and chronic urethritis. The same preparation is frequently beneficial in chronic vaginitis, leucorrhea, erosion of the uterine cervix, and chronic cervical endometritis. Lotions and dusting-powders containing tannin sometimes act favorably in hyperidrosis of the feet.

"When it can be brought in direct contact with a bleeding surface tannic acid is a reliable hemostatic. In epistaxis strips of lint spread with vaseline and tannic acid make an excellent tampon. In hematemesis or enterorrhagia the drug may be given in full doses by the mouth. As it is absorbed in the form of gallic acid, which has no styptic power, it is valueless as an internal remedy in hemorrhages outside of the alimentary canal. As it forms more or less insoluble tannates with tartar emetic and the vegetable alkaloids, it may be employed as a chemical antidote in poisoning by one of these drugs. Cantani and others have spoken highly of enteroclysis with a hot tannic acid solution (2 per cent.) in Asiatic cholera.

"*Administration.*—When its action is desired in the stomach, tannin should be given in powder; if the intestine is to be reached, it should be given in pill."—(Stevens' *Material Medica.*)

5. *Emetine hydrochloride* is used in cases of amebic dysentery, liver abscess, and pyorrhea alveolaris. It is administered by the mouth in doses of 2 grains, and hypodermically in ½-grain doses.

6. *Epinephrin* is a substance obtained from the medullary portion of the suprarenal glands of the sheep (or other animal). It is *official* under the name of Glandulæ suprarenales siccæ; dose 4 grains. *Properties:* "It is a strong cardiac stimulant, slowing the pulse-rate and affecting the heart muscle in the same way as digitalis; it is a powerful vasoconstrictor and raises blood-pressure more than any other known substance; it increases the tone of all muscular tissue; it causes diminution of peristalsis and a depression of the respiratory center, which may result in respiratory failure and death. *Uses:* In minor surgery as a local vasoconstrictor; hay fever (both internally and locally); bronchitis; bronchial asthma; congestion and edema of the lungs; cardiac diseases (here it should be employed with caution); Addison's disease; shock."—(Wilcox's *Material Medica.*)

Adrenalin chloride is employed in the form of the solution 1:1000.

7. *Paraffin* "is largely used as an emollient and protective dressing and as a substitute for animal and vegetable fats in ointments. It is bland and unirritating, and has little tendency to change. It probably has somewhat less penetrating power than lard.

"Subcutaneous and submucous injections of paraffin, as recommended by Gersuny, have been employed with gratifying results for the correction of various defects and for cosmetic purposes. They have been used successfully in preventing rectal and vaginal prolapse, in relieving incontinence of urine and of feces, in filling depressions caused by the removal of tissue, in correcting nasal deformities, etc. The paraffin should have a melting-point of from 100° to 104° F., should be sterilized by boiling, and should be injected while warm and semisolid. The paraffin is not absorbed, but remains where injected and finally becomes encapsulated."—(Stevens' *Materia Medica.*)

8. (1) Hydrargyri chloridum mite (calomel), dose gr. ss to x; used in syphilis, as a laxative or purgative, in congested or cirrhotic liver, in diarrhea, and as a diuretic. It is a heavy, white powder; amorphous; tasteless and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing. (2) Hydrargyri chloridum corrosivum (corrosive sublimate), dose gr. 1/60 to 1/30; used as an antiseptic, disinfectant, antiparasiticide, in syphilis, interstitial nephritis. It occurs as heavy, colorless crystals, with sharp and metallic taste, and acid reaction; it is soluble in 16 parts of cold water, and 2 of boiling water.

9. *Ammonium carbonate* is used as a cardiac and gastric stimulant, also as an expectorant, and in the cure of alcoholism.

Ammonium chloride is used as an expectorant, in neuralgias, hepatic disorders, rheumatism, and alcoholism; externally it is used in inflammatory conditions of mucous membranes.

Solution of ammonium acetate is used as a diaphoretic and diuretic in fevers, chronic nephritis, dropsy, and alcoholism.

10. BELLADONNA.—*Therapeutic indications:* To relieve pain, relax spasm, check sweating, as a mydriatic, for night sweats, to check griping of purgative; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, and to relieve spasmodic cough.

Symptoms of belladonna poisoning: "In the first stage, that of delirium, there are dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration."—(Witthaus.)

Treatment: The stomach should be washed out; pilocarpine may be given hypodermatically; morphine may be given cautiously during the period of violent excitement; cold applications to the head and artificial respiration are useful. There is no chemical antidote.

PATHOLOGY.

1. *Acne vulgaris.*—"An inflammation of the sebaceous gland structure and surrounding tissues. There first occurs retention of the sebaceous secretion, which is soon followed by hyperemia and exudation about the glands and in the gland-wall (*acne papulosa*), and in-

filtration of the connective tissue (*acne tubercula*), followed by suppuration (*acne pustulosa*). If the inflammatory action be severe, destruction of the gland with a resulting cicatrix occurs."—(Hughes' *Practice of Medicine.*)

2. *Acute catarrhal otitis media.*—"With the development of an acute tympanitis, the superficial structures become more or less injected or hyperemic, accompanied by a swollen, infiltrated condition of the lining mucous membrane. A serous effusion, mixed with a hypersecretion of the mucous glands, soon fills the cavity with a thin, watery fluid, or a thick, turbid secretion which macerates the mucous membrane and holds in suspension the desquamated epithelial cells. Owing to the numerous folds or reduplications of the mucous lining, the process is frequently confined to the attic, while the remaining part of the cavity is unaffected. The inner layer of the membrana tympani becomes involved in the inflammatory condition of the tympanic space, which weakens its resistance through the process of maceration and desquamation. With an extension of the infiltration to the fibrous layer, the membrane becomes so devoid of strength as frequently to rupture under the excessive pressure of the tympanic secretions. The inflammatory process of the tympanum usually affects the lining membrane of the mastoid process, to a greater or less extent, through the intervening antrum. The Eustachian tubal structures also are generally simultaneously involved, which may proceed from the tympanum, but usually results from the same causality that produces the tympanitis."—(Alling and Griffin's *Epitome on Eye and Ear.*)

3. *Pernicious anemia.*—"The blood is scanty and pale, with alterations in the size, shape, and number of the red blood cells and diminished hemoglobin. It coagulates very slowly and imperfectly. There is no increase in the white corpuscles. The bone marrow becomes fetal, red, and adenoid in character containing nucleated red blood cells, macroblasts, neutrophiles, and eosinophiles. There is a deposition of iron pigment in the liver cells and those of the spleen. The heart, larger arteries, liver, spleen, kidneys, stomach, and muscles exhibit circumscribed or diffused fatty degeneration. There is not much emaciation, although pallor of the surface of the body is pronounced. The muscles are often unusually red. Changes in the ganglion cells of the sympathetic, sclerosis of the posterior columns of the cord, softening of the lumbar segment, and atrophy of the gastric mucous membrane may be encountered coincidently. Hemorrhages into the skin, mucous membranes, and retina may also be observed."—(Hughes' *Practice of Medicine.*)

4. *Angina pectoris.*—"Various theories have been advanced to explain the occurrence of angina. That of *intermittent claudication* is based upon the analogous attacks of pain which sometimes occur in the legs when their arteries are partially obstructed. In such a case the circulation suffices for rest or restful movement, but prolonged exertion causes cramplike pain and temporary lameness (claudication). Similarly in a heart poorly supplied with blood (ischemic), or in which the driving power is defective, exertion may cause a temporary exhaustion of the muscle. This condition would be favored by increased peripheral tension, which is sometimes permanently present, and sometimes exists during an attack. It may also be produced by chill (contraction of the peripheral arterioles). But in some cases the tension is permanently low, and then we may suppose that a slight increase of work, which would be no obstacle to a healthy heart, is sufficient to cause exhaustion to a damaged one. It is in cases of hindrance to the work of the *left ventricle* that angina occurs.

Other theories are that the pain is a neuralgia of the cardiac nerves, or that it is due to tension of the ventricular walls, induced by acute dilatation. Allbutt considers that it is not truly cardiac, but originates in the first part of the aorta. Mackenzie, adopting generally the claudication theory, compares the pain to that produced by the obstructed evacuation of other hollow viscera (*e.g.*, biliary colic), and regards it as a protective reflex."—(Wheeler and Jack's *Handbook of Medicine.*)

5. In *locomotor ataxia* the posterior columns of the spinal cords and the posterior nerve roots are involved.

The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

6. *Tuberculous meningitis.*—"The pia and arachnoid membranes are injected and matted together. There is a fibrino-purulent exudate, well marked in the interpeduncular space and following the course of the cerebral vessels along the Sylvian fissures. Tubercules are found, especially along the middle cerebral arteries and arteries of the anterior and posterior perforated spaces. The convolutions are flattened, the sulci obliterated, and the cerebral substance is edematous and infiltrated with leucocytes, with occasionally the formation of an abscess. The lateral ventricles are distended with a turbid fluid containing excess of albumen and diminution of the normal Fehling-reducing agent, and great increase of lymphocytes. Occasionally tubercule bacilli are found. Miliary tubercles and caseating tuberculous lymphatic glands are found elsewhere in the body."—(Woodwark's *Manual of Medicine.*)

7. *Acute nephritis.*—"The kidneys are generally swollen, engorged, more vascular, and of red color; in the second stage the organ remains large, irregularly red, especially the cortex; the tubules are engorged and filled with epithelium, blood corpuscles, and fibrin. The capsule is easily detached, and is more opaque than normal. If the termination is favorable the swelling lessens, the vascularity diminishes, and the tubules gradually return to their normal condition."—(Hughes' *Practice of Medicine.*)

8. *Dental caries.*—"The primary stage of caries is determined by the presence at a certain portion of a tooth of an acid capable of dissolving the inorganic salts. The matrix of the prisms is the first to be dissolved, and into the spaces thus formed crowd organisms which, given a suitable pabulum, produce more acid and further destruction of the surrounding tissue. There is good reason to believe that, apart from its natural resistance to solution, the enamel offers no vital resistance to attack. After the solution of the enamel the dentine is decalcified in a similar manner, and later the remaining organic portion of the tooth substance is digested by the bacteria, which perform their work by means of secreted enzymes, digesting the tissue in much the same way as the pepsin of the gastric juice acts upon albuminous materials. . . . Dental caries is, as a rule, a progressive disease, but under certain conditions its progress becomes arrested. In such cases the teeth generally show an extensive loss of tissue, the enamel of the masticating surfaces, and even of the sides, having disappeared. The exposed dentine is darkly stained, and presents to the eye a polished appearance. An examination with a probe will show that the dentine is as hard as, if not harder, than in the normal condition. This state, which is known as *spontaneous arrest of caries*, may be found in both the deciduous and permanent teeth; in the latter the condition is most frequently met with in hypoplastic first permanent molars. It occurs only in teeth with living pulps, and the appearance of the teeth suggests that the disease, when active, was of a general and rapid character. Microscopical examination shows that the dentine retains the color of carious dentine, or is perhaps slightly darker. The dentinal tubes, which can be easily seen in the discolored part, end apparently upon the surface."—(Colyer's *Dental Disease.*)

9. *Raynaud's disease* "is a very rare disease, characterized essentially by symmetrical gangrene. The cause is unknown; but there are three chief theories brought forward to explain the disease. These are that it is due (1) to endarteritis obliterans, (2) to peripheral neuritis, (3) to vascular spasm. The affection is associated with some disturbance of the vasomotor system,

as a result of which local stagnation of the peripheral circulation occurs. In consequence of this there arise localized anemia, congestion, and finally gangrene, symmetrically distributed."—(Hughes' *Practice of Medicine.*)

10. *Duodenal ulcers.*—"As a rule, the ulcers are single, but they may be multiple. The most frequent seat is in the ascending portion of the duodenum about half an inch from the pylorus. They have a punched-out appearance, are round or oval in outline, and, if recent, are funnel-shaped, with the apex toward the serous coat. The edges are usually smooth, rarely ragged. They vary in diameter from a few millimeters to several centimeters, and may extend to the muscularis or even to the serosa."—(Stevens' *Practice of Medicine.*)

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State

The Textile Industry of Germany.—The defunction of this industry causes no immediate hardship because of paper and other substitutes. After the war the new paper industry must be fostered. Paper will be made a textile fabric, and from paper threads (textilose) bags, twine, etc., can be made. Woven in sheet form it can be used for shoe uppers and belting and for other substitution for leather. The nettle has also become a recognized textile and remarkably fine thread can be made from it. A premium of 400 marks per hectare of nettles is offered by the government. The nettle is equally valuable for fodder, especially for poultry feed. —*La Presse Médicale.*

Miscellany.

The Management of Tuberculosis in Great Britain.—Sir Robert W. Philip, writing on tuberculosis in relation to the war in the *Edinburgh Medical Journal* for May, 1918, points out that there is not time to dwell on the general adoption of co-ordinated antituberculosis measures. So far as the United Kingdom is concerned the methods had become stereotyped in the Report of the Departmental Committee on Tuberculosis. That committee recommended the creation of a network of antituberculosis schemes throughout the country, and the program was beginning to be carried out just before the war. The several elements in the scheme were being forged according to the varying needs of different parts of the country. A special tuberculosis staff was in course of selection. Everything pointed to the establishment of uniform antituberculosis activity, when the war intervened. Since July, 1914, the movement has been largely held up. Schemes which were getting under way throughout the country have been crippled or stopped. Men chosen for the tuberculosis service were hurried away to war service. Sanatoriums and hospitals erected for tuberculosis were given up to wounded and sick soldiers. Buildings of all kinds in course of erection were held up or diverted to other purposes. The stern events of war have, however, only thrown into sharper relief the urgent need for a wisely directed, comprehensive campaign against tuberculosis. With the continuance of the war there has been traceable in some parts of the country an increase in the death rate from tuberculosis. The British are still up against an aggressive infection with immense ramifications, whose ravages can only be checked and overcome by unremitting efforts along assured lines.

One encouraging fact, however, has emerged during the war, namely, that the British forces have suffered less than those of other European powers. Dr Hermann Biggs of New York has stated emphatically that France has suffered from the war in this respect infinitely more than Britain. He associates the result with the fact that in Britain the tuberculosis problem had been efficiently met before the war, while in France, on the other hand, practically nothing had been done. His statements, however, have not been universally accepted, and, as Philip says, the British must not plume themselves overmuch, but must try to estimate the bearings of tuberculosis as occurring in the British War Service. Officers and men discharged because of tuberculosis return to civil life and the State assumes certain responsibilities toward them. With this in mind fullest use should be made of expert guidance available within the services and outside, in respect of the examination of men before admission to the services and in respect of the discharge of tuberculous men and their subsequent treatment and care. Men have been admitted to the services who should not have been passed, and some have been excluded unduly. Men have not been discharged who should have been, and some discharged men might have been retained. After discharge the men have often drifted for lack of direction.

THE PHYSICAL BASIS OF WAR SHOCK.

A PLEA FOR THE MORE PHYSICAL CONCEPT AND BASIS OF TREATMENT OF THE MENTAL AND INCAPACITY DELINQUENCY OF VICTIMS OF WAR HYSTERIA AND SHOCK.

BY HOMER WAKEFIELD, M.D.,

NEW YORK.

WITH the progress of active warfare overseas, and with the participation of constantly increasing millions of men, our returning transports will bring back two types of maimed soldiers, both demanding reconstruction and reeducation; the surgical and mental cases. Both will tax the acumen and ingenuity of the medical profession to the utmost, but the latter class will probably more than the former present difficulties, both in way of immediate treatment and in reconstructive training in behalf of useful and self-sustaining after lives or careers. Should the Central Powers be enabled to hold out for a military decision a year or two hence, when our country can bring its full resources to bear, we may expect numbers of thousands of men, not maimed in body, who have suffered mental impairment through fright, shellshock, and allied causes, returned as mental or "nervous" wrecks, exhibiting defects rendering them delinquents, and until in some measure restored, dependents upon society. Such cases will present the greater difficulty because of the apparent absence of actual physical injury, on which account we may expect our psychiatrists, following the experience of France, to divide into two diverse camps or schools, based upon the purely psychical or metaphysical theory, on the one hand, and the physical or material theory, on the other. The one group will probably be treated too wholly by hypnotism, psychic impression, persuasion, and other purely mental means, while the other may too wholly ignore such measures; both of which would prove most unfortunate.

A prime objective of this paper is to set forth: (1) the absolute unity and indivisibility of the physical and the mental; (2) the mentality solely as a function of the physical body; and (3) in the final analysis, of interrelations between the mind and body, which involve quite as much influence of the body upon the mind as of the mind upon the body. Moreover, that the mentality, as a function of the physical body, is not exclusively a function of the brain or nervous system, but of the entire solid and fluid constitutents of the body, their chemical and physical status, and of the biologic reactions as dependent upon these factors.

The Psychoneuroses of War Shock.—In those cases of concussion trauma of the more delicate tissue structures, which do not exhibit macroscopic rupture or other form of broken integrity, we must not lose sight of the fact that in more violent traumas such naked eye evidences do appear, showing that the lesser ones differ in degree only. In fact, we observe that the malfunction of tissue integrity disrupted by concussion trauma is not unlike the malproduct of anemia.

The investigation of war shock has been so far baffling, only because it has not been sufficiently recognized as a genuine *traumatic* shock. That its true status has been obscured by an excess of theories regarding it, there is little doubt. Even on the part of those who look to the physical body for the lesions responsible for the major manifestations, there has been much disposition to confine the mischief done to a single organ and to seek repair by a single rectification or by an artificial supply of some particular secretory product, whereas the clinical picture should be a more general one.

The recognition of the spasmodic deflection of the major volume of blood of the body from the superficial to the deep circulation, and the asphyxial effect of such deflection upon the dependent superficial and extremity tissues, on the one hand, and on the venous stasis of the internal glandular and other organs, and upon the blood *per se*, on the other, has been conspicuous by its absence. The predisposing features, such as spasmodic phenomena of low density tissues, have likewise escaped consideration, though emotional proclivities, actual fright, and chill have been mentioned by writers on the subject. It is gratifying to note that Henderson, Crile, Van Slyke, Cullen, Cannon, and others have observed acidosis as an important chemical change incident upon impared circulation.[5]

An interesting and most significant observation made by Cannon, Fraser, and Hooper[4] is that in the onset of shock (1) the red corpuscles are apparently retained in the capillaries, (2) the blood in proportion to the extent of the shock, exhibits a markedly higher red cell than a venous count, while (3) hemorrhages further exaggerate the diversity. The obvious explanation of this is that upon spasmodic contraction of the superficial tissues, the involved capillary collapse evacuates the corpuscles of lower specific gravity and fluid constituents of the blood and reduces the capillary lumen beyond the capacity of the denser red cells to pass. Moreover, it may be implied that the muscle and integumental tissues would exhibit a much higher percentage of red cells in shock than observed in the lobe of the ear, a finger, or a toe, unless those parts were coincidently especially subjected to spasmodic local

anemia by chill. Those tissues which have been previously affected by accrued metabolic or fatigue products, exhibit hyperesthesia and correspondingly excessive spasmodic reactions. It appears imperative that all of these factors must be considered collectively in order to grasp properly the composite clinical entity, even as physical phenomena.

Non-recognition of the stasis of the rising column of blood in dilated venous trunks, its increased volume and weight coincident with the lowered blood pressure and progressive general circulatory failure may lead to disaster and death. Cannon[5] finds that acidosis increases as the blood pressure falls. Wiggers[39] suggests that a further reduction of venous pressure by bleeding would seem a rational procedure in the case of acute cardiac failure. Either that or dilution of the blood by hypertonic salt solution also further decreases the hemoglobin percentage, while conversely cases appear to be benefited by transfusion of blood after hemorrhage complications.

In this connection, the long ago ascertained fact should not be neglected that "in asphyxia the unaerated blood passes with so much difficulty through the systemic capillaries as finally to arrest the action of the heart."[15] The arterial blood, according to Flint[6] normally contains less water than the venous, but the observed fact that the capillary blood becomes more concentrated relative to the extent of the shock shows that it becomes more retentive of the corpuscle elements with the extension of constriction of the capillary luman. Cannon, Fraser, and Hooper[4] observed that "a dilution of the blood which continues to progress beyond the fourth or fifth day after injury is ominous, and the longer the dilution continues the more unfavorable it becomes," signifying the presence of sepsis.

It will be recalled that many of the survivors of the "Black Hole of Calcutta" afterward died of septic fever. Since venous blood contains a higher percentage of water than arterial blood, we may deduce that asphyxiated blood in general exhibits a fall in specific gravity as evidence of partial disintegration, despite that its red cells pass through constricted capillaries with difficulty. Swelling of these cells would also be a factor. Hydremia may be regarded as a suboxygenation sequence and as a factor of susceptibility to infection.

Resultant Physical Incapacity of War Shock.—We have long been familiar with the peculiar consequences of violent injuries of shock proportions which have borne the name of amnesia, in which the victim of a fall, a blow, a runaway or railroad accident, etc., suddenly was mentally cut off from all his past experience and consequently from its utilization in the interpretation of current sense perceptions. The obliteration of all memory, habit, and automatic activity, and in some cases of some of the primal instincts, as may be imagined, places an individual in the position of a new-born infant, with everything to be experienced and learned over again, even in the use of the voluntary muscles and the capacity for all physical expression, thus demanding vocational reeducation.*

*As early as 1789 Rey Regis, a physician of Montpellier, France, recognized the existence of a motor paralysis as depending on a lost memory of motor force, due to a lesion of certain parts of the brain. ("Natural History of the Soul," London, 1789.)

These effects may be partial or complete, and in different cases may or may not be amenable to restoration of the lost store of past experience and knowledge. Amnesia may be *simple*, with loss of memory only, *localized*, systematic or general; it may be continuous, alternating or periodic, stationary or progressive. In causation it may be termed traumatic, toxic, autotoxic, fatigue, asthenic, emotional, etc. In its manifestations, it may be predominately sensory (or perceptional) or motor. Amnesia recognized as an affection of discoordination or incoordination between the engram preamble and the motor reaction to current sense perceptions has been defined by such terms as consciousness disaggregation, dissociation, etc., which are not very elucidative as to fundamentals, causation or conditions.

Defective and inhibited functions of tissues of defective integrity, both motor and mental, must be studied as such, not as separate non-physical entities, but by determinations of faults of the underlying physical mechanism responsible for them, just as a mechanician looks to disorder in a motor when its mechanical action goes wrong.

Speculation as to how violent concussive force disrupts the vital integrity of living tissues, has not proved very productive of noteworthy solutions. However, electricity of high voltage and low frequency readily produces somatic death, whereas the same voltage of high frequency is tolerated with impunity. Whatever the wave frequency of high explosive detonations, the extreme violence with which they occur proves so destructive to the more delicate tissues, that in the more severe cases the cerebrospinal fluid becomes blood tinged, hemorrhages into the retina and conjunctiva occur, and bleeding from the ears, the lungs, the stomach, the bladder, and bowels, indicating tissue ruptures, may be induced. Later, for months after the disappearance of blood in extreme cases, leucocytes and globulines are found in the cerebrospinal fluid, indicating meningeal damage. From these ultra-serious cases one may discern the nature of the lesser ones as differing in degree but not in kind. Some degree of disorganization obtains, and restoration depends upon the minimum of damage done and the promptness with which circulatory compensation is reestablished and the progressive acidosis is arrested and neutralized with hyperdermatic injections of solutions of sodium bicarb. Adequate provision for the proper treatment of these shock cases directly behind the lines will accomplish much in the direction of a successful outcome.

The importance of prompt intervention following the experience of shock, and the unfortunate outcome of permitting time to elapse, even in the milder cases, before measures are taken to counteract the effect produced, is emphasized in artificially produced aphonia, such as by hypnotism. The restoration of these cases becomes increasingly more difficult in proportion to deferment of the same measures for its abolishment. The explanation is to be found in the fact that the tetanically contractured tissues are in a state of disintegration as a chemical sequence of physiologic tetanus. Whatever the neurotic predisposition of the patient, this result is the same in kind.

Some Physical Factors of the Pathogenesis and

Pathology of War Neuroses.—Since the war neuroses, so-called, have come to occupy so prominent a position in the catalogue of war-wrought injuries to the man on the fighting line, it seems to me that more regard should be paid to the underlying pathology, to physical conditions which predispose to the morphologic states and give expression to the typical symptoms. First of all let us recognize that the variation in susceptibility to hysterical manifestations, to shock and other typical features, between one man and another, finds expression in the more susceptible one succumbing to a correspondingly less violent perturbation. The consideration of the prime physical factor of such susceptibility carries us back to the fundamentals of the reactions of the living substance (or protoplasm) to external perturbation. No discoveries or theories concerning the nervous system have given us illumination on this subject equal to the long-accepted knowledge of the behavior of protoplasm in its reaction to environmental perturbation on the basis of its innate irritability.

When we appreciate that the degree of irritability, *i.e.* of *esthesia* and reaction energy expenditure, corresponds to the state of density of the involved living substance, we have elicited an explanation why it is that youth, the female sex, depletion by illness, inanition, starvation, chronic fatigue, suboxygenation, anemia, local and general, respiratory, cardiac, and circulatory insufficiencies, and allied conditions, produce coincidently a lowering of dependent tissue density and a corresponding precocity and overt intensity of reaction to environmental perturbations.

However great our regard for our present advanced knowledge of the nervous system, and of its physiologic function, both ganglionic and transmissional, we are in these cases gaining nothing by vaguely attributing to functional irregularities of the nervous system reactional abnormalities which *per se* account for the functional perversions when the nervous system exhibits no inherent variation from the normal, either organic or functional. Obscurantism and obfuscation have no place in scientific pursuits. Let us in time of war no longer cling to occult mysticisms however time honored are their passive acceptance. Even though the laity continue to allude to *nervous* phenomena, let us call them *irritability* phenomena.

Anesthetic and hyperesthetic phenomena exactly correspond with the etiological and pathological features of our knowledge of the characters of tissue reaction, according to the known laws of their status of irritability, and have no relationship with any known laws of any independent nervous function. All theories of etiology and prophylaxis must bear the test of exhibition of unmistakable relations of cause and effect. Unfortunately for medicine some unchallenged hypotheses that have come down to us are quite as occult and nebulous as if attributed to the supernatural. They entirely lack a scientific substratum and the superstructure is no less ethereal. Like the research man who attributes his failure to supernatural agency instead of his own incapacity, many unsolved problems of apparent functional origin have been attributed to some obscure malfunction of the nervous system, of which there exists no foundation in fact.

A development of irritable weakness is usually denominated nervous prostration, neurasthenia, an attack of nerves, etc., while the yet more obscure term *nervousness* is in almost universal use as expressive of lesser degrees of the same thing. In some mysterious manner the relationship of "nervous weakness," chorea, hysteria, hysterical paralysis, hysterical convulsions, epilepsy, hysterical tetanies and contractures migraine, asthma, neuralgia, and many paroxysmal diseases are quite generally recognized. Perhaps less intimately connected with them may be recognized Raynaud's disease, diabetes, railway spine, and war shock.

These subjects have been greatly obscured by the exhibited inability to recognize how such conditions could be caused by such immaterial causes as the emotions of fear, fright, terror, grief, intense anxiety, great depression of disappointed love, sudden loss of property, business reverses, military defeat, etc. Even characterizing them as vasomotor phenomena does not explain them. It is insufficient owing to the exclusiveness of its applicability to contraction of the muscular coats of the arterial system, mostly of the arterioles and its effect upon non-striped muscle fiber. Raynaud's disease is probably its nearest approach, but even that involves far more than arterial reflexes. It must also involve the capillary system which possesses no muscular coats yet has a capacity of five to eight hundred times that of the entire arterial system. Raynaud's disease is more typically a spasm of capillary contained striped muscle of the periphery and extremities than any other. It commences as a spasmodic exsanguination and more or less obliteration of the lumen of the capillaries. The ensuing peripheral anemia, the blanching, numbness and coldness are exhibited long in advance of the ultimate gangrene of the extremities.[26] Observers of all nations are practically unanimous in characterizing the predisposing factors by names that are now known to refer to the same underlying condition. Raynaud characterizes the disease that bears his name as a neurosis. He observes that young nervous women, hysterical individuals and children are most affected by it, and that sexual debility, fatigue, cold, venous stasis, circulatory retardations, intensive emotions, etc., are among the exciting causes.[26]

In an analysis of Raynaud's cases, it is observed as not a unity of causative agencies, but of the nature of the ultimate underlying composite causative influence. In one case a chilling produces peripheral anemia, another factor is an intense emotion, another is ergotism, etc. In still another class of cases the same causes may produce diabetes instead of Raynaud's disease or yet other diseases which exhibit the same characters of hyperesthesia as the prime predisposing factor, and of precocious and excessive reaction phenomena. In the case of diabetes we observe in one case chill produces hyperglycemia, boils and carbuncles, and another in which, following a sudden loss of fortune on the Stock Exchange, a man abruptly develops typical symptoms and becomes permanently diabetic.

Raynaud's disease, occurring as a spasmodic affection, is quite different from that resulting from ergotism. Both may exhibit the typical characters of symmetrical gangrene of the extremities, but in respect to their pathogenesis, one is the antithesis

of the other. Ergot would prove the most potent remedy for the spasmodic type. This, however, is not an example of *similia similibus curantur*, for the pathology is not the same, notwithstanding an identity of name. What, however, is true of Raynaud's disease, is equally true of other diseases, wherein the classification and name are determined by the pathological anatomy rather than by the pathogenic process involved. Ergotism is not a neurosis, notwithstanding that neurotic paroxysms may as effectually asphyxiate the extremities as ergot. Anesthetic leprosy may yet be found due in some cases to spasmodic, and in others to toxic phenomena. Bacterial infections, even with marked susceptibility, may remain atypical.

It should be stated here that an immediate effect of completely depriving a tissue of a constant supply of oxygenated blood is *anesthesia*, while the ultimate effect of a period of suspension of circulation is loss of tissue integrity (loss of density), the effect of which is *hyperesthesia* and exaggerated reaction. The unstable condition known as hysteria exhibits variable areas of both anesthesia and hyperesthesia.

When from shock, fright, terror, and other depressing emotions, the blood is determined from the superficial to the deep circulation, the entailed exsanguination of the superficial tissues necessarily involves a condition of peripheral tissue anemia, which may attain any degree, ranging from one of insignificant degree, to one sufficient to produce diabetes or even Raynaud's disease, as well as war shock. Graves' disease may result from the same effect, and lesser goiter and exophthalmos obtains in case of war shock. Chill, as well as fright, not infrequently, by exsanguinating the periphery, causes hyperglycemia and more or less acidosis, resulting in a series of boil and carbuncle developments. The blood deflections of chill of the extremities in the cold and wet trenches of certain seasons, result in trench fever and trench feet, as well as predispose to shock when shell detonations occur in too immediate proximity. In this respect privates are more exposed than officers, thus accounting for their greater proclivity to shell shock, while officers are more subject to the anxiety form.

The integrity of living tissue is dependent upon an incessant supply of blood carrying oxygen and nutritive substances. The highest integrity as expressed by the highest density, is that of the most perfect supply of the most perfectly oxygenated blood. Conversely, however, the density-integrity falls corresponding to the degree of anemia attained. The flaccid paralysis is the immediate resultant of the tetanic contraction which runs a definite progressive course, followed by exhaustion relaxation. The recuperation from this condition finds a state of lowered tissue density which remains with its ecstatic hyperesthesia of considerable anemia, and hyperemia of reestablished circulation. The alternation in these states is due to the circulatory fluctuations.

The Physical Basis of Emotion.—I know of no better way to present clearly to the reader the physical aspects of morbid emotions than to begin with a survey of the anatomical and physiological fundamentals underlying the conditions produced, and then to follow it with the clinical picture and final sequence. Let us first understand that the visceral venous system, especially the great venous trunks, by far the largest veins in the body, which constitute the so-called splanchnic venous columns of the thoracic and abdominal cavities of the torso, largely follow the spinal column. When completely dilated, the capacity of these great venous trunks is sufficient to contain nearly all the blood of the body, and in death they do contain approximately the entire volume of the blood then remaining in the body.

Under normal conditions of life, these trunks are so maintained in a state of tonic contraction that they act simply as channels of conduction of the return blood circuit rising back to the lungs and heart. When the walls of these veins are in a normal state of tone (tonic contraction) they act as the resistance box of the entire circulation of the body. When the tonicity of this vascular area is intact, the body is in possession of considerable recoil elasticity and of its maximum capacity for absorption of shock, whereas in its absence we are at the mercy of the thousand and one vicissitudes of everyday life, which otherwise are taken care of by these shock absorbers. Therefore the loss of tone constitutes susceptibility to shock, and conversely, shock, *per se*, involves lowered or loss of blood pressure.[25]

Without depreciating the importance of the above described dilatation of the splanchnic venous trunks in the great deflection of the blood volume of the body which takes place in the more violent emotions, we are inclined to recognize the more positive action of the spasmodic contraction, the recoil tetanus, of the superficial and extremity tissues which occur simultaneously with the splanchnic venous dilatation and thus serve to vacate these surface and extremity tissue areas of their capillary blood content which is, according to Flint,[26] five to eight hundred times the capacity of the entire arterial system of the body. That alone entails corresponding weakness and incapacity.

The loss of heat and normal color of the surfaces and extremities of the body, and the simultaneously occurring muscular tetany and rigidity, and more or less loss of motor functional capacity involved, are more directly related to the peripheral anemia than the splanchnic engorgement, which by its involved venous stasis exerts its major effect upon the heart, circulatory and respiratory functions. Somatic heat and motor capacity are dependent upon the superficial circulation and peripheral combustion, which in these cases is curtailed or abolished.

Whether in the last analysis the superficial circulatory system is found to be more affected by fatigue-wrought tetanies, and the dilatation of the splanchnics is more largely produced by concussion shocks such as the explosion of large shells or the most abrupt mental or moral shocks, frights, or the most intense emotions, is of less consequence. The essential effect is a dual one representing the places of departure and arrival of the deflected blood. This loss of tone is characterized by extension or elongation of the circular fiber walls of the veins. The dilation is evidence of that condition. The general relaxed state of the body is accompanied by a feeble state of the venous walls, and through it, is vulnerable to all the factors of trau-

matism. The flaccid dilatation of the venous walls is incident to the induced blood stasis within, at least in time relation.

When a person is toneless and relaxed, he is said to be in a state of irritable weakness. He is super-irritable, super-sensitive, super-excitable, super-impressionable, super-suggestible and super-credulous. His powers of resistance, of recoil, his stamina and his self-control are gone. What formerly was withstood with poise now becomes an unbalancer, an undoer. Trivial factors which formerly were of the most trifling import become factors of perturbation, disturbers of peace and of rest, and agents of excitation. That which the individual was oblivious of or proof against, now proves overwhelming of his weakened resistance.

If for any reason a person is weak and toneless from hereditary or acquired causes, from lack or absence of physical (motor) activity, from congenital defect, from depletion of illness or vicious indulgences, overwork, chronic fatigue, bad nutrition, etc., he loses in general tissue density and through it his tone, and he becomes soft and weak. With the loss of tissue density the tissue reactions become correspondingly spasmodic and paroxysmal in character. The former manifestation of that calm stability and enduring strength of sustained effort is now replaced by instability and by jerky, spasmodic, and paroxysmal movements which are so characteristic of loss of motor integrity and of coordination. They are often violent but unenduring, for the accrued energy is quickly expended.

We encounter all degrees and stages of deflective determination of the blood of the body from the superficial circulation to the internal, and of a corresponding vacating of the superficial vessels, together with a congestion of blood, in the splanchnic trunks in inverse proportion. The vacated superficial vessels are responsible for the livid blanched hue of the skin and membranes and the general coldness of the surfaces of the body. The emptying of the blood vessels in the brain is responsible for the coincident incapacity for reason, and for the loss of consciousness. The aggregate anemia of the superficial circulation, extending from the brain to the extremities, is the cause of the incident loss of sensation. Dizziness comes with anemia of the brain, and fainting with a more complete asphyxia. Both are incident to some degree of deflection of the blood of the body into the splanchnic veins, and the degree of collapse depends upon the degree of splanchnic venous engorgement. This peripheral asphyxia is most marked when the body is erect, and is relieved by recumbence.

The maintenance of normal mentality requires the circulation of at least one-fifth of the blood of the entire body exclusively in the brain. This large proportion falls below normal under many conditions, but in none so much as in those of splanchnic venous engorgement and congestion, in which event the rising column of blood returning to the heart and lungs stagnates in this great reservoir, producing volumetric anemia of the brain, even in advance of that of the other arterial and capillary circulation.

With the above fundamentals we are prepared to understand the nature of the process which is involved, when, by excited emotions and by shocks, the victim experiences superficial and extremity contraction and tetanic rigidity. Then the surfaces of the body become livid white and cold; the circulation and heart laboriously struggle with their burden of engorgement and congestion of the doubled volume of the rising column of venous blood, and the heart's function fails for the dual reason that its cavities do not fill and its muscles themselves languish for oxygen and nutrition. The vascular system of the lungs fails to adequately receive or oxygenate the blood and the individual in his air hunger yawns and the breathing assumes a sobbing and stammering character, the labored inspiration trebles the time duration of the expiration. Vague discomfort is followed by respiratory distress, the sensation of anguish succeeds to a distressing faintness, a sense of sickness eventually comes to a crisis, a change in the tide, and all the senses become blunted and vague; a sort of drunkenness, incident to the bloodless brain, is manifest. Swallowing movements, hiccough, or other convulsive manifestations supervene, then consciousness is lost.

In general, the loss of tissue density is the predisposing cause of human wrecking, and the disruption of the body's resistance box occurs secondarily, as an exciting factor of a final collapse. These are well recognized facts, and our Government is now engaged on a wholesale scale in eliminating from the embryonic elements of our army all those too unstable for the test, and in strengthening the tissue integrity and vital capacity of those who can be hardened sufficiently for the fray in the minimum time available.

The active belligerents of the world war have found that the weakling and the unhardened recruit soon falls a prey to what has been variously termed traumatic or war neurosis or psychosis, shell shock, etc., which may not only disqualify him for service, but invalid him home a human wreck. He suffers a breaking down of his splanchnic venous tone. His powers of recoil and resistance are gone. His great venous trunks have dilated, his blood sags in its rising column and fails to reach the heart and lungs in sufficient quantity to attain re-aeration, and collapse and incapacity to live in the erect posture are inevitable. When this *extreme* condition is once attained, resuscitation is attainable only to be invalided home, never to be useful as a soldier again, and perhaps incapacitated by unfitness in civil life in rare extremes.

The war neuroses are classified into the purely *mental* types and the *physical* or convulsive (hysterical) types. The abrupt and violent reactions to sensorial traumata of concussive force, and the excessive recoils which they entail, range in physical changes from none at all of visible differentiation to those terminating fatally, in which are exhibited extreme congestion and ecchymoses on each side of every superficial vessel of the brain. Numbers of punctiform hemorrhages appear at the terminations of the smallest vessels on the surface, together with a general softening and partial edema of the brain. It is interesting that in surgical shock, war neuroses, and spontaneous and revival conversions, fatigue is an important exciting cause. Also, that men predominate in the so-called spontaneous conversions and officers predominate in the analogous mental form of the war neuroses, while the subordinate privates and the weaker sex predominate in

the opposite forms. Women are also more disposed to hysteria than men. The hysterical forms of both war and civil-life neuroses are more amenable to hypnotic treatment than the others. The best prophylactic measure against the underlying fear of both war and religion is education against it; while conversely the religious inculcation of fear of death, post-mortem torments, etc., fosters war neuroses in troops. Cultivation of depressive mental emotions constitutes an unfortunate preparation for modern warfare.

A sensorial impression which is sufficiently abrupt and violent to produce a shock effect, a tetanic recoil, and a rigidity or contracture, in place of a normal reaction, is not to be differentiated between its occurrence in war and civil life, except in degree and violence of effect. Both appear in ultimate form as sterile emotions. In both cases, the fatigue factor is largely produced by the effects of prolonged recoil producing a succession of bombardments or single concussions of great force.

The war neuroses, or as the French term them: *cerebral commotions*, which are now elucidated and treated as never before by Dr. Paul Sollier, the eminent neurologist now of Lyons, are defined by Dr. Sollier as *hysterias in the raw*—elementary hysterias, in which the physical, as distinguished from the psychical, element is absolutely preponderant; whereas in the ordinary traumatic hysteria these two elements are almost on the same level. In the words of Dr. Sollier: "When we envisage the similarity of the pictures presented by ordinary hysteria and the nervous phenomena that result from shell shock, we are forced to conclude that their nature is identical. Shell shock thus demonstrates to us that hysteria may be provoked by causes purely physical, and we are led to conclude that the purely psychological theories are inexact, since they do not apply to all the cases. Since it is undeniable, on the other hand, that hysteria can be provoked by emotional and moral causes, we must conclude that there exists an entire gamut of forces—physical, mechanical, organic, and psychic—that may lead to the same clinical results."

Dr. Sollier's identification (1) of war neuroses (shell shocks, etc.) with civil life hysteria, which is mostly observed in women, in the absence of the more violent shocks, and (2) its recognition as an essentially physical affection, and best treated by physical measures, is a great stride in the proper classification of the fundamental emotional element. This final attainment in neurology is a complete substantiation of a position taken by Professor Angelo Mosso of the University of Turin, who wrote many years ago:[10] "The vivid impression of a strong emotion may produce the same effects as a blow on the head or some physical shock. There are men who, through fear, have lost consciousness, sight, or speech; others, still more sensitive, have remained for a long time paralytic, unable to move legs or arms, and have lost all sensibility. Some remain for a long time sleepless, others fall into a sort of exaltation resembling the outbreak of mental disease, many lose their appetite, or are afflicted with articular diseases, and in some the nervous system suffers such a shock as to cause violent fever." The siege of Strasburg in 1870 is cited as producing from fright, paralysis agitans, convulsions, etc. In the present war, all the above and yet greater injuries of this type abound. A painful sensation of having been beaten on the head, which is not infrequent, conforms to Mosso's classical description.

Whether from faulty synthesis or from later experience incompatible with its normal sustenance, when the vital integrity of a tissue is lowered, it is primarily and most conspicuously exhibited by a corresponding lowering of its density; and its functional performances are typically related to the phase of its coincident density, both in reaction time and in expenditure of energy. Tissue density is thus a common factor in both physical and mental cases. A lowered somatic tissue density constitutes a predisposition to the superimposed traumatic concussion of war as well as of civil life. Habitual emotionalism, the overwrought depression of distressing anxiety, and fear of religious origin, exhibit the same type of neurotic symptoms as those developed under fire. In fact, the former group may predispose to the latter. The wet-brained alcoholic exhibits psychical peculiarities not unlike victims of cerebral injury. Periodical or constant hyperesthesia is a symptom typical to both. Emotionalism and hysteria are but expression phases of hyperesthesia. The various transition phases existing between hyperesthesia and anesthesia include the wide range exhibited between the manifestation of exaltation and melancholia, and between the extremes of mania and dementia. The normal balance belongs to an intermediate phase. Typical characters of behavior: impetuosity, impulsiveness, impatience, intolerance, discontent, unrestraint, lack of self-control, etc., of hyperesthesia, thus contrast with stolidity, apathy, obtuseness, and the clouded and stupid minds of the dullard, the sluggard, and the pronounced stages of feeblemindedness and general paralysis.

Secondary Stasis in Visceral Organs.—The existence, as an initial event, of a pronounced venous engorgement and congestion, especially of the splanchnic venous trunks, must of necessity cause serious circulatory stagnations in the important visceral organs which are directly dependent. One cannot ignore the fact that the several ductless glands, notably the thyroid, thymus and adrenal, are thus seriously disturbed in their functions, while the occurrence of war nephritis, incidental to chill, shell shock and other events of the trenches, adds to our observations of chill and the greater depressing emotions, in times of peace, as etiologic factors of nephritis in general. In Graves' disease the circulatory disturbance is the most marked and constant symptom, and in nephritis also it is pronounced, though regarded more as a result than as a cause. Edemas occur in both, but in the former they are fleeting in character. Vascularity occurs in the thyroid in the former, but only in the more acute types of the latter. It is a matter of common observation that acute manifestations of thyroid swelling and exophthalmos occur in varying degrees in individuals, not affected by Graves' disease, during periods of great emotional stress and spasm, in cases of shock and other manifestations which are consequent upon the factors typical of emotion and shock conditions.

Apart from the major casualties of war rendering

men defective, there are several obscure types of pathological manifestation which render the victim vocationally unfit. Emotion sterilizes the motor reaction sequences of sense impression stimuli, by dissipation of the energy that otherwise would be focussed, differentiated, and directed to specific purposes. Inhibition, whether due to tetanic contraction or flaccid paralysis, invalidates all applied effort. Incoordination and discoordination involve defeats of those unities of collective physical and mental expression which are necessary to singleness of purpose and action of individual thought and effort. Flustration frustrates design and purpose because of rendering the individual impotent to act at the right time, or until the psychologic moment has passed.

All of the above elements of vocational unfitness are affections of physical instability. They are fundamentally expressions of hyperesthetic conditions with which the psychiatrist is called upon to deal as first in importance in connection with the rehabilitation of the war shock cases. The release of the victim from hyperesthesia must precede any efforts to train him in any useful vocational pursuits. Until that can be attained any technical training will prove an unfortunate expenditure of time and money. In many cases, out-of-door exercise and occupations of simple form should precede indoor trade trainings.

The mental pathology of inculcating (1) intense excitement and emotional stress which has no focused outcome, (2) a highly wrought tension, aborted short of its motor sequence, (3) a state ending in muscular tetany and rigidity, instead of activity, (4) a preamble of a motor reaction excited to a high degree and yet deprived of its normal sequence and thus rendered sterile, is as damaging to those organs involved in the *mental* function, as are those recognized *physical* organs which are engorged and congested, without release or alleviation, by artificial stimulations and inflammations of the states of war neuroses. In all sterile emotions, whether instigated by religious excitement and emotionalism, by alcoholic intoxicants, or unrequited love, the result is practically the same, namely, a reaction, which is made up of a combination of sense impressions and perceptions, with or without deliberation and physical (motor) expression, including speech.

Under *normal* conditions, when a sense impression is not attended by some kind of physical expression, it is because its impulses are too weak. It may be so feeble as to create no other than a subconscious impression (short of eliciting the attention). A yet stronger one may elicit a focus of the conscious attention, yet not evoke motor expression. With sterile emotions we observe a bestowal of sufficient stimulus, or impetus, to excite motor impulses, yet which are in these cases repressed. We thus have for our consideration a general physical disequilibrium which is due to an unbalanced reaction (an aborted reaction).

Sterile Emotion.—There are many causes which would create in a weak man the emotion of fear, in a weaker one that of terror, yet in a strong man anger or rage. There is often exhibited a motor stress which excites one to escape and another to combat—unless it be that it is so excessive that it is sterilized in tetanic contraction. According to the observations of Cannon[5] of Boston, the disability of one or the capacity of the other, are dependent upon the capacity of the suprarenal and thyroid glands to secrete substances called *epinephrin* and *thyroid secretion*, which, as internal secretions, play a dual role in reestablishing the equilibrium of the general circulation. It appears that a profound *normal* emotion is attended with the secretion of epinephrin and thyroid secretion, by virtue of which motor reaction is assured with circulatory compensation. Conversely, in the event of the sterile emoton, we observe the determination of blood to the venous trunks, muscular collapse, fear, capitulation, etc. But also in such cases we may find glycosuria, albuminuria, air hunger, etc., which are also symptoms of adrenal insufficiency; while muscular twitchings, tremors, spasms, and even tetanic convulsions occur from derangements of, and disequilibrium between, these glandular organs.

It is to be observed that wholly *normal* individuals exhibit an elasticity of recoil which is indicative of a certain capacity for shock absorption which is only shattered by concussive shocks of such violence that the integrity of the involved tissues is disrupted or destroyed, which may be to such a degree that it would be attended with fatal sequence.

The unstable individual exhibits a conspicuous absence of such a margin of safety, of elasticity and capacity for absorption, and in perhaps what Dr. John J. B. Morgan[6] terms "potential neurosis," there is a disposition to react to potential perturbations by tetanic recoils, recoils that simply serve to develop a state of biologic tetanus, in which state the involved tissues remain, and thus causing contractures of the extremities instead of the *normal* reaction, *i.e.* constituting a contraction of normal intensity, followed by relaxation.

The inhibition of normal motor response in the face of powerful artificial incitement of such a reaction, is responsible for the cumulated dynamic stress that finds expression in the exhibited state of tension, and eventually when the resistance powers of the organism are overwhelmed, finds vicarious outlet, and the normal exit being closed, it finds escape in a diffuse tetany or an impulse wave which pervades the entire motor organism. This we term emotion. It is a sterile substitute for utilitarian action.

Having thus once forced such a false passage, as it were, of subsequent vicarious energy escape, which by this channel is facilitated; and as multitudinous repetitions not infrequently widely open this path, the victim correspondingly finds his endurance for resistance so lowered that trivial vicissitudes of daily life attain to emotional reaction and energy escape. We say the individual is unstable, restless, unenduring, impatient, intolerant, and moreover *irritably weak*, because he lacks the strength which stability involves, because he lacks control of the emotional responses to factors of irritability, and is hysterical because of the typical emotional and spasmodic character of the expressed physical phenomena.

This condition may be regarded as analogous to a steam boiler with a safety valve which has been regulated to blow off steam at so low a pressure that no accrued power is accumulated, and all machinery

requiring other than the lowest ebb of kinetic energy is unmoved by it. The vicarious discharge which is abnormal in sterile emotions, is quite identical with that diffuse wave, so typical of what we also call emotion, which accompanies the orgasmal discharge of the connubial function, and I attribute to this fact the explanation why sterile emotions, originally of religious character, so often recur as typical sex or pervert sex emotions and later reappear repeatedly with all their characteristics and accompaniments, as such.

Under normal conditions the current impression impulses accelerate allied past impressions to a repetition of their past reactions and into an associative reaction with the current one, culminating in a unified motor expression. If conversely the individual be emotional, the motor reaction is manifested as a diffuse wave-like flow that lacks definition and unified direction.

An emotion of terror may fail to focus into a definite act of defence or flight, and thus be expressed as a general muscular contraction, a tetany or rigor, or as a general muscular flaccidity. In either case, paralysis of action supervenes. An emotional wave in the form of a thrill is equally diffuse and sterile as a motor expression. The inability to hold the impulses to the normal paths is obviously a manifestation of physical weakness.

In an hour of peril, a person of physical strength and high integrity of animal efficiency will experience a reaction characterized by focus, direction, and definition of action. The weakling under the same circumstances will be overcome and frustrated, he will in common parlance lose his head. We say his will is paralyzed, but in truth the elementary factors that go to make up the will fail to materialize, and the volition in turn is absent. The accrued energy which might have taken form as a voluntary act flows away as a diffuse wave, or is exhibited in a general muscular contracture. It is therefore in the form of either a diffuse emission of kinetic energy or of a muscular contracture, a sterile and defeated (abortion of a) voluntary act.

Present space will not permit going more fully into their elucidation, but it is not infrequently the case that functional abnormalities are in reality perversions, wherein the abnormal function, while a perversion of the function which is disordered, is or would be normal to some other function. An action which is in harmony and equilibrium with one organ, office, or function, would usually be in disequilibrium with another, and thus its action, in the vicarious capacity, constitutes a derangement which is basically a disequilibrium. When functional abnormalities occur in connection with the mental function, we term them unbalanced states, which they are in truth.

Kennedy[47] characterizes as *flabby* the typical physical feature that bears strain badly, as distinguished from the *robust type*. These are most misleading terms. Hyperesthesia is the type which is especially vulnerable, whereas there are asthenic types which are more anesthetic than hyperesthetic, which are decidedly flabby. Conversely, many men who might be well characterized as robust, in the usual acceptance of that term, are without recoil endurance or resistance. A type of man exhibiting supertensity or tenseness of attitude, together with considerable degree of so-called robustness, generally makes a poor showing of toleration of the vicissitudes and perturbations of anything like modern warfare. As deaf mutes are determined good material for aviators, so may men of blunted sensibilities be found to best withstand the violence of concussive commotions. When the requisite physical status is not procurable in sufficient numbers of physically hardened sound men, the safer increment must come from the unsound of *bluntcd* rather than *exaggerated* sensation.

Peripheral and Somatic Acidosis.—Peripheral and general acidoses are observed both locally and somatically in the type of cases under consideration. Instances wherein tetanic states, spasmodically acquired and tetanically perpetuated, are productive of superacid generation, are now readily recognized, not only by the biochemist but by the chemical pathologist and the well informed physician in general practice. Not only is sustained tetanic contraction attended by disengagement of sarcolactic acid as a cleavage product, but when wide areas of peripheral and extremity tissues are involved, the incidental exsanguination of the capillaries and the entailed asphyxia produce a degree of multiple acid formation which indicates arrested tissue synthesis.

Approximately universal peripheral exsanguination involves pathogenic conditions which, however, extend far from the periphery. Whenever any large vascular area is approximately vacated, we may be sure that the visceral venous system is in inverse ratio over-engorged and congested, and such a condition of stasis is of little if of any less importance as a factor of retardation and inhibition of the general circulation. The over-distended and over-weighted splanchnic venous trunks then constitute a serious menace to the ascending flow of blood when the body is in the upright position.

The rises of blood pressure occurring in contrast with the general circulatory failure of these cases, are probably related to the coincident acidosis. Stefani[28] ascertained that dyspnoic blood produced local vascular dilation and central constriction, which in general would raise blood pressure. Bradford and Dean[43] have shown that on producing asphyxia in a curarized animal, a great rise in arterial tension occurred, followed by a more gradual fall. The relation of vascular tone to the alkalinity of the blood seems to be established by Leonard Hill's findings that the vascular tone is increased by raising the alkalescence of the blood.[16] In general, conditions exhibiting asphyxia are productive of a fall in the alkaline reserve (acidosis).

Oertel and Grawitz[40] have been largely instrumental in showing that a marked polycythemia form of concentration of the blood is found in conditions characterized by chronic stasis, cyanosis, and edema, and that this is more marked in the capillaries than in either the veins or arteries. Lazarus Barlow[42] has given us at this point a most explicit illumination by determining that the withdrawal of the blood from one part of the body, in the course of a deflection to another part, is accompanied by a rise in specific gravity in the tissues which thus become anemic. Taken collectively, many important points are elucidated by these investigators.

The physiological course of reaction events followed by tissues subjected to devitalizing conditions, appears to be governed by the degree and abruptness of the effect. When sufficiently severe and abrupt, cell death occurs in the phase of contraction. When conversely the effect is insufficient to produce cell death, following a varying period of exhaustion flaccidity, vital recuperation follows. When the devitalizing factor is a peripheral and extremity spasmodic exsanguination, there is observed an alternate succession of contrasting events. The antecedent and predisposing low tissue density, often attended with hydremia, is primarily succeeded by a sudden ejection, especially of the watery elements into the deep venous trunks, leaving a marked inspissation of the blood remaining in the capillaries, which in turn, as a compensatory process, takes up water from the tissues. When, as in Raynaud's disease, the asphyxia is sufficient to produce extremity tissue death in this phase, its form would be predestined to be dry gangrene. Conversely, however, when instead, it is followed by exhaustion flaccidity and a passive hyperemia, low tissue density reappears in increased degree, and perhaps hydremia or edema, or both. Intermediate between tissue death in contraction and flaccid paralysis, we observe the more common forms of rigidities, contractures or clonic contractions of the so-called hysterical events, and between vascular exsanguinations and passive hyperaemias we have fluctuating variations in the specific gravity of the blood.

Collateral Susceptibility.—Over thirteen years ago[56] and lately[57] I directed the attention of the profession to the coincidence of susceptibility to bacterial infection with hyperesthetic neurotic manifestations, as due to the common cause of the lowered tissue density, the infection occurring as a direct result to the incidental lowered surface tension and osmotic pressure of the involved cells and coexisting lowered vital reaction. Among the many factors of reduced tissue density, none are more rapid and pronounced in their causative action than those exsanguinating reactions which have so long been grouped under the caption of vasomotor reflex actions.

The present war has afforded us remarkable instances of coincident extreme spasmodic exsanguinations of the tissues, especially of the lower extremities, which are attended with those typical characters which have come to be known by the general term *war neuroses*, in relation with a virulent infection recognized as *trench fever*. Furthermore, it has been a remarkable general observation that conscripts in an abrupt transition from civil to military life with its rigorous discipline, strenuous drilling and other intensive training, its fatigues, weather exposures, etc., before general hardening has been attained, and in some cases owing to belated supplies of proper clothing for experienced cold weather, have been affected with pronounced super-susceptibility to virulent infections.

It is not without interest that recorded observations of the effects upon hardening of men in the first, second, and third years respectively, of service in the German Army, for the period from 1867, following the Austro-Prussian war, to 1874, excluding one year of the Franco-Prussian war, of 1870-1, exhibit the attained extent of hardening in terms of specific gravity of tissues, and show clearly the relation of same to their experienced reaction to surface cold, and susceptibility to the then prevailing infectious diseases.[46] The second year of service exhibits degrees of tissue hardening greatly beyond those of the first year, and those of the third year are well in advance of those of the second year. The then most prevalent infectious disease, typhoid, showed only a half to one-third in third-year men what was exhibited by first-year men. A similar decrease was shown in the derangements due to exposures to cold—chill. Since the German Army counts on the first year of service to weed out the weak men who pass the examining physicians, it is not surprising that its officers have deprecated the physical efficiency of the American Army made up largely of first-year men.

Gustave Jaeger,[46] who presented the above-mentioned statistics, quotes some most interesting tables from Beneke exhibiting the relative percentages of water, salts, organic solids and fats of the arm bones respectively of a soldier, a woman affected with tuberculosis, and a boy dead of caries, and from Ranke, of percentages of solids of muscles, brain, spinal marrow, and blood, of a decapitated young healthy criminal and of an old man dead of marasmus. These two tables show the remarkable loss of solids, or inversely, increase in proportion of water, in diseases which involve a loss of tissue density. In the latter case, the loss of solids incident to disease much more than offsets the usual loss of tissue water incident to old age.

The value of hydrogogue catharsis, diuresis, and perspiration as artificial and natural measures for the active elimination of water from the blood, is recognized as essential for the maintenance of high degrees of tissue integrity, and incidentally immunity from both infection and pathologic chill reactions. The same might be said of emotional reactions, the proclivity to which would be greatly lessened by all measures which lessen the proportion of tissue-contained water.

Relation of Manifestation to Severity of Case.—In considering symptoms in relation to the severity of morbid causes, it may be accepted that *hyperesthetic* manifestations are significant of lesser degrees of disorganization than the *anesthetic* type. All progressive mental declines exhibit mania in early and dementia in late stages. Traumatic neuroses exhibiting amnesia, apathy approaching dementia, accompanied by deafness minus central labyrinthine disturbance, are far more serious than those exhibiting hyperesthetic symptoms. Exhaustion *anesthesia* is to be recognized also as the transient end result of processes attended with *hyperesthesia*, emotion, and their exhausting trains of manifestations.

In some cases the severity of manifestation appears out of proportion to apparent causative factors. In these cases the physician must look to the predisposing factors, both remote and recent. Even emotional experiences, either violent or repeated, religious as well as profane, serve to predispose to excessive and precocious emotional spasms of pathogenic import. Alcoholic indulgence, fatigue, chill, and many distressing and depressing experiences predispose to excessive emotions. The

etiological factors of emotion and of spasmodic and paroxysmal diseases in general, are practically identical. Individuals exhibiting proclivities to emotion, generally also exhibit the spasmodic as well.

An individual exhibiting that diathesis which we identify as a proclivity to fluctuating abnormal extremes of motor reaction, and as characterized by instability, emotion, hysteria, etc., is correspondingly lacking in motor control, and aggravations of the primary condition from any cause, correspondingly increase the existing motor incapacity, which is fundamentally volitional, and is thus truly an organic disease of the will. We observe a disruption of continuity between the physical preamble of the individual's reaction to sense impressions and the normally resulting motor sequence, and moreover, that correction of the defect must compass a reestablishment of coordination between the two. In bad cases a more or less complete reeducation must be considered.

Education in its wider sense involves experience, and general experience further involves the exercise of all of those physical functions which participate in that somatic attainment. The disruption of reactional motor coordination involves a corresponding destruction of the underlying physical mechanism which is responsible for all animal automatism, habit and memory, such as the accrued sequence of all past experience. Just as the original coordination, both motor and physical, was developed under the law of repetition, so all reestablishment of the same must be attained by a systematic and methodical exercise of the fundamental vital reactions to rebuild that complex superstructure which is so essential to the self-sustaining man.

What we term voluntary action is differential and discriminatory, corresponding to its volitional attributes. Volitional incapacity is not necessarily characterized by a weakness of motor expression, but by an incapacity to differentiate, focus, direct and control it. It is rather a problem of conservation than expenditure of energy. The unstable and the unfit individual is characterized by precocity of and excessive motor expression, by impulsive and immaturely reasoned acts, and by lack of restraint and control of same. The lower the grade of voluntary motor expression, the less differentiated and focused, and the more diffuse it is. The lowest and most sterile form of motor reaction is that diffuse wave which we term emotion. In a sense, it is a vicarious escape of potential energy, an emission of what might have, in a person of higher tissue integrity, been conserved and accrued until capable of motive power, whereas as an emotion it is characterized by sterility in the economic sense.

All factors that inhibit the development, or accomplish the disruption of tissue integrity, correspondingly lower its capacity for utilitarian functionation. Anæmia, local and general, cardiac insufficiencies, circulatory impediments, etc., are common causative factors, but those events, spasmodic and paroxysmal, which asphyxiate the extremities and the periphery to a sufficient degree to engorge and congest the visceral venous system, are the most notable.

Mental Deficiency and Motor Incapacity of Hyperesthesia.—The present form of estimation of mental capacity by various mental tests on the basis of age equivalents, fails adequately to differentiate the imbecile from the temporarily disqualified hyperesthetic. The former type is one of maldevelopment; the latter is, on the other hand, a disability dependent upon abnormal function affecting mentation. The former is a sluggish, subsensuous condition, while the latter is a hyperirritable and hyperexcitable (hyperesthetic) one. The former is attended with functional deficiency, the latter by precocious and excessive functional reactions. It is obvious that these two diverse states should not be diagnosed by the same test as a unit condition.

The hyperesthetic individual, in any effort to focus and sustain the attention, may experience a cramp-like reaction, an emotional or spasmodic rigor or tetany of the involved organal tissues which effectually precludes adaptation of mental activity. The greater the stress of the occasion, the greater is the inability to exercise the mind with proper direction and definition. During a test or examination, these cases will in vain strain to think, to reason, or to remember, yet as soon as the paroxysm passes off and relaxation supervenes, the much sought mental goal is attained with ease. We therefore have exhibited in this class of cases, in one respect, the very antithesis of the actual feebleminded ones; yet in another respect the end result is the same. With regard to the biologic over-reaction status the antithetical processes thus prevail. On the other hand, the enfeebled effort to perceive, to discern, and to discriminate does not *mature* in the *first* case, and conversely it is inhibited in the *second* one. The ultimate result of the test is the same; the mental goal is equally minus. The application of a mental test to a recruit might in either type be attended with the same result, namely, with failure to pass on tests which it is deemed he should in accordance with his actual age. In the first case it is through permanent mental incapacity, and in the second it is through spasmodic onset of tetany which effectually precludes the exercise of the requisite mental activity.

Human documents afford us abundant illustration of the instances wherein even approximately normal persons, in the anxious moments and stress of educational and military examination, are utterly unable to recall answers to questions and solutions to problems with which they are perfectly familiar, and recall them with celerity as soon as relaxation supervenes, when the examination is over and it is too late to make it available on the test. This same experience is observed in progressively greater degrees corresponding to the exhibited degree of hyperesthesia.

As the degrees of hyperesthesia mount higher and higher, the stress of *anxiety neurosis* increases correspondingly. Unit degrees of stress are produced with correspondingly decreasing causative factors. An overwhelming fear of not being able to think of correct answers to questions, accomplishes the inhibition necessary to make such recollection impossible, in much the same manner that stage fright incapacitates an inexperienced public speaker.

The inability of an individual to summon and utilize his faculties of discernment and of discrimination, involving the interaction of current with past performance impressions, relegates his mental level to the normal equivalent of earlier years when the total impressions received corresponded with those of their present utility. This also corresponds with the comparison of the equivalent mental levels of immature minds in adults which measure to those of childhood.

Flustration and Frustration.—Prior to our consideration of volition or exercise of will, there should be preceded a concept of its underlying antecedents, which may be traced backward, beginning with the individual's completed resolution or will to do. Underlying all volition is the *decision*, underlying decision is *discrimination*, and underlying discrimination are many originally competing factors, the predominant one of which has become the dominant factor in the ultimate volition which is attained by a species of natural selection, *i. e.*, by virtue of the exclusion of the minority factors. Volition is thus the more or less definite outcome of a complex process; it constitutes the ultimate goal of the collective mental process. Its expression may be emotional or a matured motor act. The will is not always perfect or normal as a unit first cause of voluntary acts. The mechanism of its complex process is subject to many misarticulations and disequilibriums of its constituent factors. The concert of reaction of its constituent factors may be unbalanced in both energy and time relation, with an exhibited ultimate sequence varying from one extreme of explosive violence to another of paralysis; which may be alternately manifested in an unstable person as reaction expressions of divers degrees of perturbations. The paralytic or inhibitory process which we observe in the cases of flustration and frustration, in which the antecedent psycho-physical process fails to come to a focus, leaves the individual in a state of mental confusion and distraction minus the normal crystallization into volition.

Definiteness of orientation, of direction, and of focus of expressed volition depends upon a clean-cut singleness of goal. Conversely, to the extent that thought is confused and disconcerted it is diffuse, ill-defined, and correspondingly weak. The most perfect expression of individual volition is that of highest definition and most exclusive direction. These elements involve the final focus.

The typical hyperesthetic individual is characterized, not only by indecision, irresolution, vaccillation, inconstancy, fickleness, caprice, unreliability, irresponsibility, disloyalty, and treachery, but by imperfections of the mechanism of volition synthesis. This, however, is as unstable as is the individual's character in general. Excessive motility on one occasion and complete inhibition on another is the expression of the instability.

A typical feature in the hyperesthetic is the inability to mature an elaborated reaction when disconcerted even by trivial perturbations. Such an individual is characterized as fussed or panic-stricken whenever anything occurs that might excite activity, as flight or a combative response in a normal person; and they exhibit flustration or a mental confusion, which involves frustration, or perhaps a physical inhibition of all motor initiation, and thus the defeat of the voluntary acts.

Such types of physical and mental incapacity are serious obstacles in the way of all hyperesthetics, as soldiers. They are especially incapacitating at times of surprise and under the usual stress of emergency. Incapacity to endure the strain, stresses, and concussive shocks of warfare may cause the mentioned incapacities to be increased to such degrees, and coordinate volition may as a consequence be so deficient that delinquency may result. Presence of mind in emergency is indispensible in the army and navy, and in after civil life it is a most valuable asset. It is antithetical to those discoordinations, disaggregations, and dissociations of mental unity which spell incapacity to the individual.

Individuals rendered hyperesthetic from all causes, are more or less prone to experience superstress on all occasions demanding emergency resourcefulness. Each effort is thwarted by a spasmodic reaction which may be succeeded by a tetanic or rigid contractile state. The greater the exigency making demands upon the memory, or upon the mental capacity involving sustained attention and application, solving more or less difficult problems, etc., and the greater the effort made to comply, the greater is the exhibited proclivity to be attended by spasmodic response phenomena and by a tetanic state continuing with the incidental stress. When these cases are permitted to continue uncorrected for a length of time, they become habitual, and chronicity supervenes under the law of repetition. These individuals become confirmed victims of flustration.

Flustration is of interest and importance to the army medical service owing to its victims being disqualified for aircraft and other military service in general requiring either morale or capacity for emergency resourcefulness. A man who is overcome with sterile emotion, or is, as it were, frozen stiff and immobile during periods of sudden emergency stress, is much better off well in the rear of army fighting lines. The production of flustration states, as part and parcel of war neuroses, is a subject of prime importance. The incurrence of shell shock may, in the milder cases, leave the victim apparently little the worse for the experience, yet on the first occasion of its repetition or in the stress of an urgent emergency, he may fail at the crucial moment to signal, defend or retire, as the occasion demands.

Apparently the term *war shock*, in its broader sense, is made to cover a wide field of mental and physical manifestations resulting from the violent factors of war. By some writers it is caused to cover practically all of the resultant manifestations covered by the more general term *war psychoneuroses* of other writers. It is, however, true that concussive forces of lesser import, but of the same general order, produce obscure injuries which are not closely allied to those of major importance, and that lines of demarcation between the two are difficult to draw.

The production of a complete flaccid paralysis in one part or case, a state of painful cramp rigidity or contracture in another, of hyperesthesia or anesthesia, of exaggerated or lost reflexes, and

tremors, according to their location, are indicative of the degree of affectation. In general, the distal extremities are most profoundly affected, and the fingers or toes are the parts which become cyanotic, when a case exhibits it other than as of *general* circulatory failure. Anesthesia is also most exhibited in the distal extremities and in cases where it is not universally peripheral. The degree of its extension toward the torso bears an approximate relation to the extent of the affectation. In this connection it is of interest and importance that Dr. Sollier explores his cases for anesthesia in the direction extending from the distal extremities toward the torso and begins his treatment on the sensitive side of the line of demarcation, extending it from that point toward the extremity.

Treatment.—A distinct and most noteworthy advance has been made by Dr. Sollier in this therapeutic procedure, which we can best appreciate when we recall how much time has been lost in past years in subjecting completely anesthetic tissues to stimuli of all the five forms of physical energy, namely, mechanical, electrical, thermal, photic, and chemical, they necessarily exhibiting no reaction and therefore attaining no therapeutic result. By his wise procedure of beginning his physical stimuli above the anesthetic area where reaction is attainable, the influence upon the more distal contiguous anesthetic areas is rendered potent. Progressive extension of the resanguinification toward the distal ends of the extremities carries with it restoration of sensation, and motor capacity gradually follows with the application of massage, manipulations, and exercises which are rapidly followed regardless of the hyperesthetic and even painful reactions that are thus produced.

The best results in these cases are obtained in those in which anesthetic paralysis of an extremity has existed for a minimum period of time. It is therefore important that provisions be maintained to treat these cases properly in the shortest possible time after incurring the shock complex. Especially those cases which can never safely be returned to the trenches obtain the best results from the earliest possible treatment. This, I understand, is already generally recognized and provisions are under way to carry out the promptest treatment possible.

Hypnotic suggestion is of value only in the milder cases of war neuroses, as anything like an *exclusive* treatment. For the re-establishment of circulatory equilibrium, it is less prompt and efficacious than the physical measures. It is, however, in all cases a valuable accessory treatment for the control of hysterical phenomena, as symptomatically treated.

It should be emphasized that the circulatory failure of shock is least exhibited immediately following the primary deflection of the blood from the superficial and capillary to the deep and venous system. Following this initial event, supervenes progressive circulatory failure and acidosis as a sequence of superficial tissue asphyxia and splanchnic venous stasis. These events should be intercepted at the earliest possible moment. To accomplish that end, not only should brisk frictional rubbing or brushing of the surfaces of the body be promptly resorted to, but hypodermic injections of adrenalin or ergotin should be administered repeatedly until contraction of the dilated splanchnics is attained sufficient to reestablish circulatory compensation. Following this a progressive system of exercises, first passive and resistant, and secondly active and gymnastic in character, may be carried out to surprising advantage. Machine massage and gymnastics are contraindicated.

The shorter the period and the less the extent of circulatory discompensation obtaining in individual cases the less will be later losses of motor coordination. These cases are, however, best treated by a series of reeducation drills of those movements which appear most difficult of volition after the acquirement of the so-called shock neurosis. Those cases in general that are not amenable to a happy treatment outcome will be those unsuccessfully treated in their earlier stages, and those in which vital tissue integrity is damaged beyond repair.

For recondensation and retoning of dilated venous walls adrenalin will be found more powerful and prompt, but more transient in action than ergotin, which will be found more reliable, safer, and more enduring in its action. The latter is especially preferable for repeated use. By the use of ergotin, wisely administered, many of the symptoms typical of war shock, including the tachycardia, will disappear early and thus greatly simplify the after-treatment. Cardiac and circulatory failure will in most cases be averted by *early* restoration of general tissue condensation and tonicity, in which the heart as well as the vascular walls participate.

Hyperesthesia, emotional instability, tachycardia, insomnia, passionate outbursts, epileptoid attacks, spasmodic and tetanic proclivities, contractures, functional paralyses, etc., are more or less benefited or eliminated by the hypodermic administration or ergotin in a series of daily or more frequent doses, as introduced by Livingston a number of years ago. Separate treatment for the nausea, sense of precordial griping and oppression, gaseous distention and dilatation of the stomach, etc., is not usually required.

Cold baths, wisely administered, will prove valuable in these cases; and on occasions when the patients do not exhibit reaction glows to warm towel drying and brisk rubbing of the body surfaces, they can be accelerated by carbonizing the bath water, or adding pine needles or mustard sufficient to produce mild rubescence. Thermatic hot-air, vapor, steam, and water baths are distinctly harmful in ultimate results, and should be resorted to only in emergencies and in the absence of better methods.

We would emphasize the importance of the earliest possible attention to the newly experienced cases of war shock by prompt rectification of the induced disequilibrium of the general circulation and followed by such other corrections of exhibited derangements as may be indicated in individual cases. These fundamental disorders may be adjusted without explaining to the patient possible consequences of deficiency of the treatment, or neglect, other than on his own part, and

without relaxation of military discipline. In those cases where a radical rehabilitation of the normal circulation is promptly attained, the case may, after more or less treatment by cold baths and exercises, be returned to duty, while those suffering actual structural injury, and who remain incapacitated after circulatory restoration, should be sent to the rear for repair and rehabilitation of tissue integrity. The most serious cases should be invalided home. The latter class are not infrequently so shattered physically that they are quite incapacitated for ever again withstanding the intense anxiety, stress and shock of battle. Their recovery demands prompt and complete removal from the war zone, but not release to independent civil life. These cases should now be entered upon the new phase of rehabilitation which is at once to save them from social delinquency, and prepare them by a combined physical and industrial reeducation for future usefulness and self-support.

Prophylaxis.—A proper regard for prophylaxis against the war-wrought neuroses as a class must begin at the cantonment, in exercising discrimination in the determination of the time duration of the period of training and physical hardening necessary, preparatory to the production of a stable and well-poised soldier, who can be depended upon in the presence of the perturbing and discoordinating exigencies of the battlefront. It is obvious that from the viewpoint of the physiologist, the custom of giving all men the same time duration of training is a mistake. Not only do men differ greatly in their aptitude for the manual of arms and field maneuvers, but even more greatly do they differ in their condition of physical hardness or softness. The ultra-soft recruit may require from one to two years to become as hardened as another at the end of six months. The soft recruit may, however, at a later period, be made as hard, enduring and efficient as his originally hardy comrade, by a corresponding prolongation of his training. With that greater hardihood also, he would thus become correspondingly more tolerant and resistant of the exhausting contingencies and vigils, chills and infections, commotions and shocks to which he may be subjected. If the war long continues, time will permit selection of men for short and prolonged adaptive periods of training, which will insure their more uniform hardening, and thus by compensating the softness of a certain proportion of recruits we will correspondingly lessen the number vulnerable to the experienced incapacitating factors, which all must face on the field of battle. Men rejected for early service may be hardened for later service by simple prolongation of their training. Such training should be more carefully gauged in intensiveness.

TREATMENT OF EMPYEMA BY THE CARREL-DAKIN METHOD AT THE WAR DEMONSTRATION HOSPITAL, THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.*

(PRELIMINARY REPORT.)

By GEORGE A. STEWART, M.D.,
NEW YORK.
MAJOR M. R. C., U. S. ARMY.

In the War Demonstration Hospital at the Rockefeller Institute for Medical Research we have treated a number of cases of empyema following pneumonia. As many of these cases have been of a peculiar type an entirely new problem has been presented. All have been treated with the Carrel-Dakin method. These cases had first been admitted to the Rockefeller Hospital as pneumonia cases and then transferred to the War Demonstration Hospital after the development of empyema.

As this is to be a discussion on treatment, I will merely mention that the usual physical examinations, *x*-ray, thoracic punctures, and cultures of the pleural fluid, were employed in all cases for diagnostic purposes. The case was considered one of empyema if on thoracic puncture macroscopic pus was found, or if pus cells and organisms were demonstrated by the microscope.

This evidence was considered sufficient for operation, and some cases were operated on as early as the third day after the onset of the pneumonia. The longest period which elapsed before operation was 120 days. This patient has been aspirated in another hospital seven times. Our operations were performed under local anesthesia, novocaine 1:400. The operation of choice has been rib resection, opening into the pleural cavity and exploration with the gloved finger or instrument, opening all pockets. The site of operation in those cases where the fluid seemed to be evenly distributed has been at the lowest point posteriorly, and in most cases over the eighth or ninth rib in the posterior axillary or scapular line. In those cases where a definite localized pocket was found the opening was made over the region of the pus.

In the early cases the pleural cavity was not flushed out at operation. Three to five Carrel perforated tubes were placed in the cavity extending to all points, and two large short tubes inserted in order to have a free outflow of secretion and chlorinated material. With our later cases the pleural cavity has been flushed with Dakin solution at the time of operation, the large tubes have been omitted and four Carrel tubes stiffened with fine silver wire have been placed, endeavoring to reach all parts of the cavity. Compresses wet with Dakin solution, replaced the large tubes originally used, in order to prevent a too rapid interchange of air. After placing the tubes and compresses, *x*-ray examination showed that the tubes reached all parts of the cavity.

In the early cases instillations of 30 to 60 cc. of 0.2 per cent. sodium hypochlorite solution were given every two hours for forty-eight hours, and as no contraindications arose in the use of this solution the strength was increased to 0.5 per cent. sodium hypochlorite, or full-strength Dakin solution. In our later cases instillations have been given every hour during the day and every two hours during the night, and the amount has been increased to from 80 to 100 c.c. Dakin solution. This has been done to follow more closely the necessary principles of time, concentration, and contact in the use of an antiseptic.

Dressings are made daily. A smear from the inside of the pleural cavity is taken to be examined microscopically, the cavity is flushed out, the individual tubes are tested, and fresh tubes inserted when necessary. Compresses wet with Dakin solution are then placed in the external wound as at operation, the skin is protected with vaseline compresses or zinc oxide ointment, and a cotton pad and chest binder applied. The external dressings are changed by the nurse when necessary.

In our first cases closure took place spontaneously in from three to seven weeks, no attempt being made to suture the wounds. In the later cases, however, we have made secondary closure with suture when sterilization was obtained as shown by the bacteriological curve, and in some cases by culture as well. Cultures taken at the time of dressing have been found sterile at the end of five to nine days. In this way we were able to close cases in from five to twelve days or more, the average time being about fourteen days. Primary union was obtained in about 70 per cent. of the cases. When secondary sterilization was necessary this was readily obtained in all cases in a week or less, and complete closure was the final result. The secondary infections were always found to be of a low virulence.

After operation the patients were comfortable and were, in general, free from the toxic symptoms present in most empyema cases. The secretions have been small in amount and free from odor. The temperature has dropped, as a rule, after operation, and in a few cases where it has remained elevated this has been due to the pneumonic process which was still active, or else to complications, since practically all of our

*Read at a meeting of the American Association for Thoracic Surgery, June 10, 1918.

cases were operated upon before a crisis or lysis.

We have treated up to the present time forty-five cases. With the exception of five of these cases the entire treatment was carried out in our hospital. These five cases were sent to us from other hospitals with sinuses that had been discharging from three days to three months. The ages of the patients have varied from fifteen to sixty-eight years. We have had thirty-two cases of streptococcus infection, nine cases of pneumococcus infection, and four cases in which it was impossible to isolate any one type of organism.

At operation we have found in the great majority of cases the fluid to be perfectly free in the pleural cavity. The character of the fluid was usually thin and watery, of a greenish, yellowish, or brownish color, and in some few cases thick, creamy pus. In a number of cases a large amount of fibrin was present, covering the pleural surfaces, and with irrigation large shreds were washed away.

Complications other than those to be mentioned in autopsy findings have been three cases of abscess of the buttocks, three cases of acute tonsillitis, and one case of scarlet fever. We have had twelve deaths in this series, nine of which have been of the streptococcus groups. At autopsy we have found pericarditis in five cases, together with one or more of the following lesions: cervical adenitis, mediastinitis, miliary tuberculosis, intestinal ulcerations, peritonitis, numerous small lung abscesses, and small kidney abscesses; one case of general tuberculosis, three cases with pneumonia involving the opposite lung, and a beginning fibrinous pleurisy. In three cases we were unable to obtain autopsies and cannot state the exact condition present.

No case has been discharged from the hospital with a sinus. All wounds have healed clean and solid. Chest examination has shown the lung to be practically normal, judging from physical and *x*-ray examinations. We have been able to return cases to duty in twenty-one days after operation. One case had pneumonia, empyema, operation, sterilization, closure, and was ready for duty in twenty-six days. The average length of time in the hospital after operation has been fifty days. This seems rather long, but we have often kept cases saveral weeks for demonstrative purposes. Not a case, to our knowledge, has been discharged from the Army or Navy for physical disability. All have gained in weight—one as high as 36 pounds. We have discharged in all twenty-two cases and some of our soldiers are now in France.

In this small series of cases, summarized in a brief preliminary report, we have found it possible to use the Carrel-Dakin method of treatment of empyemas with very satisfactory results when careful attention has been paid to all the details of its application. The series of cases has not been large, but the ultimate results obtained—forty-five cases treated, twelve deaths, eleven still in the hospital under treatment (five of which are about ready for discharge), and twenty-two cases discharged, the comparatively short stay of patients in the hospital, and their ability to return to active duty—well demonstrate the value of the method in the treatment of empyema cases.

FEDERAL EFFORT TO PROMOTE THE SCIENCE OF VETERINARY MEDICINE.

BY MAJOR R. W. SHUFELDT,

WASHINGTON, D. C.

MED. CORPS, U. S. A.

NOTWITHSTANDING all its horrors, all its costs, and all of its privations, a great war often stimulates an industry here, a science or an activity there, in one people or another, that, had it not been for the application of so severe a cautery such pursuits would have lain latent for generations to come.

This is precisely what is to be seen to-day in this country of ours; for, while the unprecedented world-struggle proceeds—a struggle that has no parallel in history, and which has already destroyed half a dozen nations and shaken the affairs and the equilibrium of the world's races from pole to pole—when it is all at an end, and the affairs of men settle down to normal conditions once more, we shall find, notwithstanding that we have

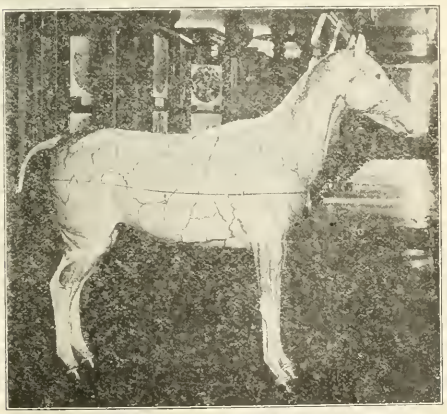

FIG. 1.—Right lateral view of the horse, skin removed and showing the superficial circulation beneath. Auzoux model (Paris); natural size. Coll. Army Med. Mus.; reduced.

poured out our life-blood and our billions in unmeasured quantities, that the years of bloodshed and losses have not been altogether barren, with respect to forcing forwards many activities that make for the advancement of true civilization and enlightenment.

It is not the purpose of the present article, however, to demonstrate this fact, or to flashlight the places and institutions where the proof of it is already in evidence; any intelligent and observing person will be able to verify what is meant.

As has elsewhere been pointed out, the old Army Medical Museum, of the Surgeon General's Office at Washington, represents at least one of our famous centers of learning and instruction which had passed into a state of almost total inactivity and slumber, through the too long continued and mellow notes of the pipes of peace. These had induced the aforesaid somnolency, and consequently further checked its advancement, until a war or an earthquake should once more arouse it to action and to a state of normal activity. This has now come to

pass. One has but to visit the building to become most thoroughly convinced of the fact. I have already, in previous articles, dwelt upon these aroused activities, and the manner in which they were manifesting themselves, while, up to the present time, the matter of the establishment of a museum and school of veterinary science has scarcely been touched upon. What is meant here by veterinary science includes the teaching and exhibition of all such material as will, in a way, demonstrate what is included in the modern, up-to-date literature on the anatomy, physiology, and treatment of all those animals usually designated as domesticated ones. Special reference, however, is made to the horse, the cow, sheep, dog, swine, and some dozen or more

Fig. 3.—Right lateral view of the skull of a colt (*Equus caballus*). 2510, Comp. Anat. Sect. Fine example of cyclocephalus. Photo by the author; reduced.

others, as well as quite a number of various species of fowls and other feathered forms.

A great many works on such subjects are already to be found on the shelves of the vast library of the Army Medical Museum, though not nearly as many as there should be. Then, too, in the museum section of the institution, upwards of two hundred specimens are met with which illustrate the anatomy of the ordinary quadrupeds which

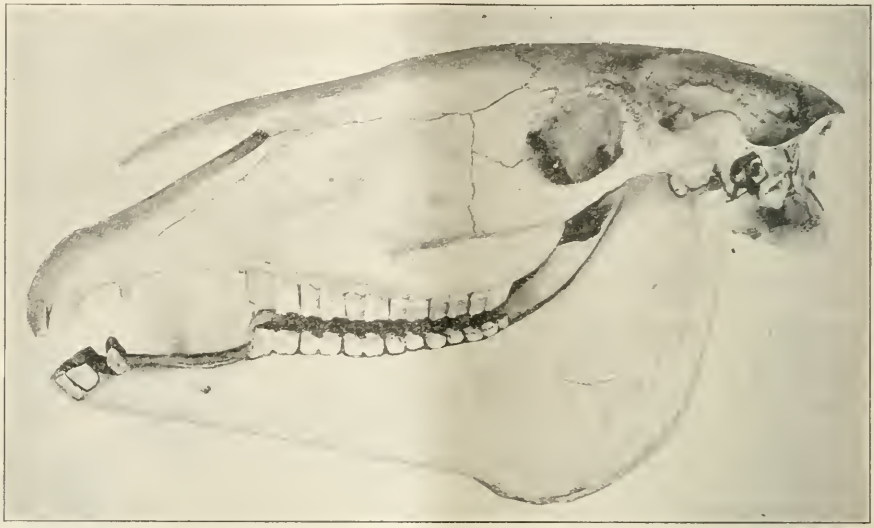

Fig. 2.—Left lateral view of the skull of a horse (*Equus caballus*); No. 34. Vet. sect. Army Med. Mus.; reduced.

man has had for ages under domestication and employed to meet certain of his ends in life. Formerly, these specimens drifted into the collection in a meaningless sort of way; while at this time it is intended to segregate them, with the view of founding a distinct department of veterinary science, building it up along the lines suggested in a previous paragraph.

Already there are to be seen in the halls and cases of this museum a number of superb models illustrating the anatomy of the horse and other domestic animals, and several of these are of the most expensive and elaborate character. For example, the horse shown in Fig. 1 is an Auzoux from Paris; it is of natural size, and may be taken entirely apart, so that separate muscles, structures, and organs can be handled separately. In the cut the superficial circulation is shown, while the model opens along the longitudinal line extending from chest to flank. For class-work and the teaching of the gross anatomy of the horse, this Auzoux model certainly constitutes very fine material.

There are models of many separate organs of the horse and other domestic animals in this collection, as well as various wet preparations. In teratology many equine monstrosities may be found for study, as well as those of the list of animals mentioned above. Very perfect examples of bones, though few in number, are upon exhibition, giving normal skulls and long bones of the limbs. (Figs. 2 and 3.) This part of the veterinary collection stands much in need of extension; for example, we need complete, mounted skeletons of the horse, cow, sheep, pig, and so on, as well as

serial disarticulated sets of the same. This offers opportunity to veterinarians all over the country to send in such specimens; they are greatly needed and will be much appreciated. The museum aims to offer, within its rooms, every possible facility for study to the members of the veterinary profession the world over. It will include for the purpose material of all kinds, and, in addition to what is mentioned above, microscopic slides (normal and pathological tissues); operations in the projecting room; therapeutics; instruments; parasites; diseases of all the organs and structures; surgical injuries—indeed, every department to which veterinarians give their attention.

Owing to lack of room, this collection cannot be made very extensive at the present time—in so far as exhibition goes; on the other hand, it is hoped that Congress will soon appropriate the necessary means to build the New Army Medical Museum, and when that is an accomplished fact there will be ample space at hand to make the exhibition what it should be—and coequal with some of the fine veterinary collections of Europe.

In that the members of the Veterinary Corps of the Army may now have before them the necessary material to study the anatomy and the diseases of the horse for war purposes—which is an extremely important matter—the collection of pathological specimens could be increased to great advantage. Such material as is shown in Fig. 4 of the present article is especially instructive, it being a case of *Laminitis*, wherein there is excessive thickening of the hoof. A medium, longitudinal section was made, showing the lengthening of the hoof and ankylosis of the navicular bone to the coffin bone.

Veterinarians of the American school, both military and civil, are already much interested in this new enterprise which the Army Medical Museum has put on foot, and it is an interest which will rapidly increase when the practical side of the movement is appreciated and the opportunity for teaching is fully developed.

ARMY MEDICAL MUSEUM.

A TORN CERVIX VERSUS UTERINE INERTIA.*

BY EUGENE R. CORSON, B.S., M.D.,
SAVANNAH, GA.

THE history of medicine has many chapters devoted to myths and myth-makers. Man loves the play of the imagination, and while we can trace many will-of-the-wisps to imagination run riot, we can also trace the beginning of many a great discovery to this same wonderful faculty. The scientific use of the imagination is a right royal gift, but its users are few and far between. Man in his quest after the causes of things has followed many a lost trail, and often failed to get back even to his starting point.

It is interesting to study the wonderful influence of mere figments of the brain, as evanescent and delusive as Virgil's phantom of Anchises, *"Par levibus ventis, volucrique simillima somno,"* until someone calls a halt and looks for something tangible and visible, and the phantom vanishes into thin air. How long malaria was but a miasm hanging over a marsh, until Laveran picked out the material thing under the microscope. How long ty-

*Paper read before the Georgia Medical Society, March, 1918.

phoid fever was also a miasm, a sewer gas escaping from defective plumbing. Their number is legion.

When I first studied obstetrics we were taught to press down firmly the uterus after the birth of the child until it felt hard like a baseball behind the pubic. There was no sewing-up of the perineum if torn, and the cervix was not even mentioned. The dangers of post-partum hemorrhage were long and graphically dwelt upon, and so was that grim monster, uterine inertia. The remedies were legion. There was always the dose of ergot. I have heard a physician dilate eloquently on the wonderful effects of vinegar over the abdomen and as a douche. The great Robert Barnes, whose truly great work on "Obstetric Operations" always seemed to me to be the last word on the subject, vaunted the great value of perchloride of iron in the uterus for post-partum hemorrhage. Think of it, and not fifty years ago! My copy of his work is dated 1876, and I find on the fly leaf that I reread it in 1878 and for the third time in 1879, and I can still recall the pleasure it gave me. And yet he mentions the dangers from hemorrhage from the torn cervix, and the advisability of suturing the torn perineum. But uterine inertia was the phantom which blocked the road and obscured the vision. The real cause of uterine hemorrhage was uterine inertia and the open uterine sinuses of the placental site. I must acknowledge that I long labored under the spell of this same myth, and as I look back I can recall many hours of dread and anxiety and sleepless nights while hypnotized by this spell. So few of us stop and think, and so few of us stop and look.

Some years ago I had a simple labor case where there was no perineal tear but a bad hemorrhage which kept up in spite of pressure and ergot, until I brought down the cervix with a sponge-holder and found a deep bilateral tear with the branches of the uterine arteries spurting an inch or more. That case dispelled for me the bogey of uterine inertia. I sewed up that cervix with catgut and went home without any thought of my patient but one of absolute security. The spell was broken.

Let us stop and look at the subject in a rational way. The uterus is a muscular bag with a good strong draw-string. And not only that, its longitudinal, transverse, and oblique muscular fibers all tend to meet their lines of force at the apex of the cone. Tear this draw-string and focus of contractions and you not only tear open the branches of the uterine arteries but your uterine contractions have lost their *point d'appui;* the lever has lost its fulcrum. A normal uterus without any cervical tear, contracting firmly after expelling the child, compresses the uterine arteries and practically stops hemorrhage from the placental site. But the torn uterus contracts but half heartedly and you get a double hemorrhage, one from the torn vessels and one from the placental site, although hemorrhage from the placental site I cannot believe to be serious, except under most unusual conditions.

Now I am not pretending that there is no such thing as uterine inertia pure and simple, and hemophilia, too, to cause post-partum hemorrhage, and even death, if you please, but I believe these conditions to be very rare, perhaps one-tenth of one per cent., just to give you a figure.

The literature is full of cases of late secondary hemorrhage, often severe and sometimes fatal. I beg you, before you make a diagnosis of uterine inertia or hemorrhage from the placental site, to inspect the cervix and look for a tear, in this case probably deep, and where an ulcerative process has opened up the uterine artery itself. You will probably find the uterus soft and boggy from trauma and from infection, conditions which could have been obviated by a little simple surgery after delivery.

And furthermore, I would state with emphasis that if you sew up the torn cervix you can omit ergot, pituitrin, and whatnot, and firm pressure over the tender uterus, and save your patient's stomach and much pain besides, and that you will have another example of plain ordinary surgery taking the place of drugs. The day for the routine use of ergot is passed.

But more important still, this minor surgery will have reduced your raw surfaces open to infection, and there will be less charting of temperature for the nurse, and more comfort for the patient. By this simple precaution you will have prevented the exposure of the parametric tissues to the external infections, tissues so rich in lymphatics. This means a shorter convalescence and perhaps the prevention of chronic invalidism and further more serious operations. If I have learned anything in my obstetric work it is that the proper sewing-up of torn tissues reduces or wholly eliminates the complications of the puerperium.

As I close this short paper you may say, "But this is all very evident and well known to us." I ask you, do you practise what you know? The great Italian monk of the fifteenth century, Savonarola, had for his motto: *"Tanto sa ciasenno quanto opera,"* which may be translated, "So much one's real vital knowledge, so much one's work." It seems that the mere abstract knowing of a thing is not all that is necessary to make that knowledge productive, it has to be vitalized by a certain depth of penetration, so to speak, a certain moral conviction of its truth, a certain emotional reaction, to drive that conviction home and make the knower a doer. When you have had some bad cases of post-partum hemorrhage and have pulled down and exposed the cervix and have seen the free hemorrhage from the torn tissues you will then have become a real knower and doer, and when, after you have sewed up snugly and firmly the torn parts, and the hemorrhage stops completely and you go home without an anxious thought or feeling, your experience, that much abused word, has made you a knower and a doer, at least when it comes to the proper treatment of the patient after delivery.

As I write this paper I pick out of the MEDICAL RECORD for January 12, 1918, the following excerpt from a Norwegian Journal.

Case of Atonic (?) Placental Hemorrhage.—Arnesen relates a case of a primipara, aged 26, who up to gestation had been strong and healthy, while gestation had been normal save for initial severe vomiting. Labor was normal and the placenta was expressed by Crede's method. Blood and blood clots followed the placenta, and there were absolutely no uterine contractions, death seemingly impending from acute anemia. The author was forced to compress the abdominal aorta. Massage accomplished nothing, and pituitrin was not available. At the risk of infecting the woman the author inserted his

hand into the uterus and, having found no retained placental debris, resorted to bimanual compression as recommended by Brandt. After fifteen minutes benefit was apparent. The patient also received supporting injections of camphor and gave no further trouble. She had lost from 1.5 to 2 liters of blood. The puerperium was afebrile.

In this case of post-partum hemorrhage the writer himself was in doubt of the origin of the hemorrhage, for his diagnosis of atonic placental hemorrhage is guarded by an interrogation point. This shows that the cervix was not inspected. Had the cervix been examined the origin of the hemorrhage could have been determined, for an intact cervix would have shown definitely that the blood came from within the uterus.

He omits the one thing needful for a diagnosis, and, more important still, for the proper treatment of the case. He, too, is under the spell of the phantom. He goes in "on all fours" and the patient gets well by the grace of God. To me, clinically, the case was one of torn cervix, the proper sewing-up of which would have controlled the hemorrhage and saved the patient all the risk and possible future complications.

The case teaches a great lesson and supports, I believe, the contention I make in this paper.

10 Jones Street, West.

THE IMPORTANCE OF REST AFTER MEALS.

By PHILIP GETSON, M.D.,

PHILADELPHIA, PA.

Life is composed of a chain of processes, of rings of functions, its continuity depending upon the harmonious correlation of all the factors concerned, making the rings firm and the chain complete. If a factor becomes deficient a weak point forms, a link dissolves, the chain breaks, life ceases. To live, to be well, we must breathe, eat, work, rest, sleep, play. Not only must the sleeping, the breathing, the eating, be of the right kind and proper amount, but they must also undergo subsequent changes in proper directions or their utility becomes incomplete, their object imperfect, their ends unaccomplished. Certain processes in the human physiology, such as respiration and heart action, are automatic, self-adjusting, self-controlling, and can not be neglected or interfered with to any rapidly injurious extent, while others, such as sleeping, resting, eating, are voluntary, under one's own control, and are to be wisely regulated, or harm to health and life will inevitably come.

Just as the action of the mechanical engine depends upon its coal fuel, which is eventually transformed into energy, so the human machine similarly depends upon its food-fuel for energy and action. To have the living apparatus act properly, to maintain the various processes of life symmetrically, to obtain a maximum of vital efficiency, certain conditions must go with the intake of food and its transformation into material available for body purposes. It must be of the right quantity, quality, and proportion. It must be well cooked, masticated, swallowed, digested, absorbed, assimilated—transformed into living tissue of one kind or another. It then becomes ready to furnish body nutrition, heat and energy.

Briefly, the organs concerned in the transformation of food into tissues—metabolism—are the mouth, pharynx, esophagus, stomach, small and large intestines, collectively making up the alimentary canal, and the alimentary appendages or accessory organs of digestion, such as the teeth, tongue, salivary glands, stomach, and intestinal glands, and liver and pancreas.

The food is ground by the teeth, softened by the saliva, passed through the pharynx and esophagus into the stomach. There it is retained, according to the amount and character of the food, for one, two, or more hours for the action of the gastric juices, the fluid secreted within the stomach. This transforms it into liquid chyme, a substance ready to go into the duodenum, where it undergoes further and more important changes.

Passing rapidly from above downward, the food current slackens as it descends, the metabolic processes increasing in importance until when it reaches the lower end of the small intestine digestion and absorption, especially the former, are practically complete.

The salivary glands in the mouth, the mucous elements in the esophagus, the hydrochloric glands in the cardiac portion of the stomach, the pepsin factors in the pyloric portion of this organ, the multitudes of glandular bodies imbedded within the walls of the intestines, the pancreas, the liver, all the millions and billions of the secreting cells situated in the mucous membrane, the inner covering of the entire food apparatus, from the mouth downward, become remarkably active when alimentation—mastication, digestion, absorption—is assumed. The many enzymes, the chemical—water—decomposers; the various ferments, the biologic exciters; the mysterious hormones, the chemical messengers; the numerous highly complex, imperfectly understood substances variously termed "biologic," "physiologic," "anabolic," "catabolic," begin to work incessantly. One cell stimulates the other, one substance actuates the next one, one factor hurries its neighbor, rushes its fellow. Each helps the other to act, to create, to filter, to secrete, to manufacture the various essentials out of the blood until the organs concerned in metabolism become one widely engorged, injected, swollen, red, weeping mass, pouring its fluids into the various portions of the food apparatus, where it is most needed, in a most economical way, so that the progress of the vital phenomena of metabolism may continue successfully, and plenty of available material for nutrition, construction, and repair of the body may be present. Not only the parts directly concerned in metabolism, but those indirectly and remotely assisting it also display great activity. Organs such as the ductless glands—the adrenals, the thyroid, the parathyroids, the pituitary body—undergo important changes, and participate intimately in the processes of metabolism. And all these energetic executions, enhanced functions, augmented phenomena, are performed at the expense of the blood. In response to a series of highly complex, minutely complicated nervous stimulations, through vasoconstriction and vasodilatation in the different portions, parts, and particles of the body, streams of energy-laden blood are directed toward the digestive organs carrying "raw" material from which the various digestive substances are produced, as

well as bringing kinetic—acting—energy for their own indispensable work. This, and such phenomena in general, namely, the propulsion of blood whither it is most needed, occurs automatically, unconsciously, involuntarily, without our knowledge or direct control. It constitutes one of nature's laws destined to preserve health and prolong life in as economic and efficient a form as possible. The importance of not interfering with such laws, with physiological functions that have for their object the maintenance of health and prolongation of life needs no emphasis. Surely the source whence heat, energy, nutrition, repair, and construction of body tissues come should command our utmost care and attention. The alimentary organs must be kept in a healthy, robust condition, so that they may be capable of performing their essential work in as perfect a mode as possible. The richness and fullness of the blood stream that is so vital a factor in enabling these organs to perform their functions adequately enables them also to keep well. Consequently, the abundance, the ease and freedom of the flow of blood-current toward the food apparatus and its associates; its strength, momentum and velocity, its force and rapidity of motion, must not in any manner be deviated from its course or in any way be interfered with.

There are various factors within or without the limitation of human control that do not permit a careful adherence to these axioms, these self-evident truths. The body, as a whole, may be anemic, poor in blood quantity or quality, the blood that is to be utilized for digestive purposes will be correspondingly poor. Metabolism, as a result, will be inefficient. The blood may be distinctly diseased. It may be loaded with excesses of normal waste products, or it may contain abnormal wastes—poisons formed as a result of disease or perverted body functions. The organs concerned in metabolism will then be poisoned by the toxins brought to them by the blood, their functions will naturally become imperfect. The mucous covering of the gastrointestinal tract may be injured by animal parasites, vegetable bacteria, and their poisonous products. It may be eroded or ulcerated through food irritants, alcoholic excesses, fermentative or putrefactive processes. The glandular elements situated within that apparatus become involved in the degenerative processes and cannot do their work effectively. The body may at some points be firmly constricted by tight bands or improper dress. It may, through faulty posture, be badly twisted or sharply bent, the blood vessels form acute angles which impede the flow of blood toward the gastrointestinal canal and its appendages and accessory aids. Digestion is thus impoverished. Other organs, those not concerned in metabolism, may, at the height of digestion, be kept active or overactive, and as tissues at work require more blood than tissues at rest, the blood that is essential for purposes of digestion may be detained in the parts that are at work, not enough being left to supply the needs of the instruments of metabolism. Furthermore, as every body action is always followed by an equal and opposite reaction resulting in the formation of poisons of quantity and strength corresponding to the intensity and prolongation of the action, the activities of one's voluntary organs occurring simultaneously with those of the organs of digestion must necessarily result in an overloading of the system doubly with the by-products of work and by-products of metabolism, both as similar as detrimental in their influence upon health and life. Hence the frequently encountered autointoxication, self-poisoning, the economy, producing more waste than it can eliminate, becomes overloaded with it, oversaturated, becomes self-intoxicated.* (See my paper on "Food and Drug Idiosyncrasy," published in the *Interstate Medical Journal*, Vol. XXIII, No. 7.)

The importance, then, of complete and sufficient rest after meals is self-evident, and needs neither argument nor emphasis. It is simply a question of health's progression or retrogression, a problem which may finally resolve itself into "to be or not to be." The entire body must either rest during active digestion, so that enough blood, enough energy remain unoccupied and go toward the metabolic engine, enabling it to do its work properly, maintaining health, prolonging life and body efficiency in general; or the voluntary factors—the hands, feet, brains, eyes—work in conjunction with the alimentary machine, withdraw the blood from where it is most needed, deprove digestion and assimilation, lay the foundation for morbidity by starting a vicious circle where poor metabolism promotes disease and disease encourages poor metabolism. That the picture just portrayed is not a product of imagination, but a condition existing wide and broad throughout the numerous avenues of life where the nation's masses work, is a fact too evident to be doubted. The time allowed the laborer, the clerk, the teacher, the office man, for a meal is usually one-half, occasionally one hour. This is consumed either in going to and from the place where the meal is had and in actual eating, or "bolting" the cold lunch at the place of employment, swallowing it without adequate mastication, while the time necessary for stomach digestion of an average meal is about three hours. The result of such imperfect equilibrium of body activity, metabolic work on one hand, and voluntary work on the other hand, is the wide spread of alimentary disorders, so prominently encountered in this country. In European industrial centers an equal amount of rest is allowed, but the work in itself is slower, easier, not so rushed, less intense. The proportion of "stomach catarrhs" among the laboring classes is there correspondingly less, while among the rural population of the Old World, where the conditions of rest are good, these "catarrhs" are hardly present at all. The same is more or less true of the American inhabitant of the country district, while among school children chronic gastroenteric diseases are, with an occasional exception, absent altogether. (I have in this respect studied about four thousand children under my care in four Philadel-

*The blood in health is alkaline in reaction. This enables its hemoglobin to carry oxygen throughout the body tissues, which is of prime importance to all forms of animal life. Activity, voluntary or involuntary, causes an oxidation of the essential constituents of the blood, resulting in formation of poisonous complex acid by-products which decrease the alkalinity and increase the acidity of this fluid. Rest enables the liver, kidneys, lungs, and skin to neutralize, break down, and eliminate the formed acid substances and thus restore the normal alkalinity of the blood and therefore its capacity for carrying oxygen.

phia public schools, and found this an absolute fact.) The number of metabolic disorders among a particular class of people is inversely proportional to the amount of rest after meals and directly proportional to the intensity of the work in general. The more the rest and the less intense the work after the intake of food the better the digestion and absorption and the fewer the gastrointestinal disorders are found. Referring again to my observations in Philadelphia public schools, the number of the disorders in question is almost nil, their number increasing as the pupil advances in years and studies, and apparently progressing in leaps and bounds as the pupil leaves school and enters the field of life's vocation, the insufficient postalimentary rest then producing its morbid consequences promptly. The topics dwelt upon are facts the observer cannot help noticing everywhere—in the urban centers of Europe, among the laboring masses of the United States, in the hospital dispensaries or in the public schools.* The improper cold lunch and the rapid mastication play their role in the production of these troubles, but they themselves are products of haste and inefficient rest.

And not only has nothing been done throughout the centuries of progress and civilization to combat and counteract this abnormal state of work, food and rest, but conditions, as I pointed out several times, are actually constantly getting worse. The one-day-a-week rest established thousands of years ago by founders of religions and patriarchs of nations was good enough in the days of yore for the ancient man, worry free, unmarred by problems of turbulent civilization, but certainly not for the modern man, burdened by uncertainty, anxiety, competition, rapid locomotion, machinery with its rush, dangers, incidents, and accidents, a life full of nervous stress and strain. Under these circumstances the old one-day-in-a-week, the ancient form of rest, steadily increases its morbid influences on the overworked, exhausted apparatus of digestion and assimilation. Surely, something ought to be done in the direction of ameliorating this neglected, deplorable state of affairs.

The economic value of such a measure is beyond dispute. It will render both better health and better work, and "health is wealth" says an old proverb. The pungency of the epigram is not only proverbial, but can actually be measured in dollars and cents. The food that is more expensive is of better quality, renders more nutrition, heat, and energy, and conversely the more nutrition, heat and energy it renders the higher its pecuniary value. But in order that the food may yield these desirable results it must undergo a series of changes within the gastrointestinal tract. The more perfect these changes are the more nutrition, heat and energy the food furnishes the better the object for which food is highly prized is accomplished. In other words, the longer the rest the individual is allowed after meals the more perfect the digestion and the more abundant its final products are the higher the worth in dollars and cents of the food utilized.* But is it necessary to argue on bases of economy where a question of public health is concerned?

The problem is a serious one, and is assuming constantly growing proportions. A point has been reached where this regrettable condition is beginning to jeopardize public health, aye, national health. Something ought to be done to give our children prophylactically, and our toilers actively, more rest and less study, less work after meals to insure rectification and perfection of the vital processes of digestion, absorption, and assimilation.

Epitome.—1. Life depends upon the proper correlation of all the physiological processes of the body.

2. Metabolism is a complex physiological process of utmost importance, furnishing the body with nutrition, material for repair and construction of tissues, heat, and energy.

3. The organs concerned in the metabolic functions depend upon the blood for energy and "raw material" from which they produce the various substances essential for digestion.

4. In response to that need, the system, through a series of nervous stimuli, directs a rich stream of blood toward the alimentary organs, so that their work may progress uninterruptedly.

5. Any tissue at work requires an increased quantity of blood for its increased activity. If, then, tissues not concerned in metabolism are at work during active digestion the blood is drawn away from the gastrointestinal tract and the food apparatus does not get sufficient blood for efficient work, the result is necessarily unsatisfactory.

6. In order that the blood may flow freely toward the organs in question it is essential that the rest of the body remain quiescent during active digestion.

7. Any action in the body, voluntary or involuntary, is followed by a corresponding production of wastes which are poisonous in nature. If the work is moderate, and followed by sufficient rest, the waste is removed by the diverse organs of elimination. If one works during active digestion the system becomes overloaded doubly with the products of metabolism and those of work. The body thus becomes autointoxicated—poisoned with its own toxins.

8. Impaired digestion causes anemia, and anemia handicaps digestion. A vicious circle is thus formed which often leads to fatal results.

9. The amount of after-meal rest of the modern worker is practically nil. The sequence is the numerous broad and widespread disorders of the gastrointestinal tract and its associates, as well as numerous diseases stimulated indirectly by bad digestion.

10. The condition described has about reached a stage where the health of the nation is becoming endangered, and unless the growing evil is remedied promptly it threatens to assume such proportions as to become beyond control.

1301 E. Moyamensing Avenue.

*In the study of hundreds of cases in the neurological clinic of the Mt. Sinai Hospital I have found almost without exception all patients suffering from chronic gastrointestinal disturbance of one kind or another. Figures which I intended to collect became superfluous after I found these conditions practically "universal."

*The body takes in a certain food material, retains some of it for body needs and gives the rest of it off as excreta. This is termed the balance of matter. Sufficient rest after meals enables the body to retain more food material, eliminate a more perfectly broken-down waste, absorb a purer final digestive product, obtain better nutrition, more heat and energy—secure a more profitable "balance of energy."

Military Medicine.

Hookworm Infection in the Army.—In certain of the Southern States, perhaps in Georgia and Florida notably, hookworm infestation is of frequent occurrence. It follows that among the enlisted men drawn from these States, there may be expected a considerable number of cases of this debilitating and troublesome form of infestation In order to arrive at an approximate estimate of the prevalence of the disease Captain Robert A. Kielty, M. R. C., and Major C. W. Havercamph, M. C., U. S. Army, conducted a survey for uncinari Americana among 8,277 soldiers, who had resided in Southern States. The findings resulting from this survey, published in *The Military Surgeon*, March, 1918, were valuable and instructive. Georgia led in the number of cases with the large percentage of 23.3, while West Virginia was low with 0.5 per cent. Several interesting points were brought out. For example, the influence of uncinariasis on the incidence of typhoid fever was suggested by the following figures. The positive cases gave a history of typhoid in 227, or 15.0 per cent., while the negative cases gave 705, or 11.4 per cent. This indicates a slight predisposition to this disease. The incidence, 932, or 15.1 per cent. of the total, gives the figure for potential typhoid carriers in the entire camp. Comparing this with the present incidence of typhoid at the camp in which the investigation took place, suggests the value of antityphoid prophylaxis and what might be expected if this procedure were not carried out.

Parasites other than hookworm were not especially sought for, but when found were noted. The eggs of taenia and tricocephalus dispar were the commonest. In discussing the investigations the authors point out that the importance of this survey lies not in the interesting data obtained but in the final results attained by treatment. Every aid given to the physical welfare of the fighting man will make the percentage of the fighting units efficiency that much greater. In the insidious nature of the infestation with hookworm, which takes the stamina out of the individual, which makes him a thin, stoop-shouldered, anemic skeleton, ready to receive any infection coming along, and once infected leaves him without combative resistance, lies the importance of a survey for its eradication.

The following conclusions were drawn from the survey: (1) 6,159 examinations of feces for uncinaria eggs were completed; 4,504, or 24.4 per cent., were found positive; (2) the work was accomplished in less than a month by a detail of fifteen enlisted men with the cooperation of regimental surgeons in the collecting of specimens and the administration of treatment; (3) oil of chenopodium was used in approximately 5,000 doses without untoward manifestations; (4) reexamination of all the positive cases, three weeks after treatment, is now in progress and indicates that good results are to be looked for; (5) a second treatment has been given in a few cases and a third and fourth is contemplated, until all cases are cleared up as nearly as possible; (6) the outcome of such a survey should result in a more efficient fighting force, a diminished susceptibility to contagious disease among the men and an increase in resistance, should infection be contracted.

Treatment of Open Wounds.—With regard to treatment by pastes Capt. W. Bernard Secretau, writing in the *Clinical Journal* for June, 1918, says the best known and by far the most used paste is bipp, which is applied according to the following technique. The wound is explored with the finger and cleaned by means of dry sterile gauze, which is thoroughly rubbed into every recess. Gentle curettage may be required. The cavity is then mopped out with methylated spirit and dried with gauze. A good coating of bipp is next applied to the whole surface of the wound by means of the finger on gauze. The wound may then be plugged with gauze impregnated with bipp, which is left in for six or seven days, or, better, partially or wholly sewn up at once. In wounds of a chronic nature, which although septic have not produced pyrexia or other signs of toxemia, Secretau always endeavors to suture. He admits that he does this, such is his faith in bipp, without having recourse to a pathological investigation, as is usual in the Carrel-Dakin method. The outer dressing, whether the wound be plugged or sutured, is of dry sterilized gauze.

As for treatment by infection with the Reading bacillus, Secretau says that the discovery of the method arose in rather a romantic manner through the salt pack treatment. Major Joyée noticed that certain cases which had been salt packed failed to acquire the characteristic foul odor, and, strange to say, these very cases usually did badly. On talking over the matter with Dr. Donaldson, it occurred to them that in the evil smelling and successful cases a bacterium was present which was absent from those which did not smell. Eventually Dr. Donaldson succeeded in isolating from these foul-smelling wounds an anaerobic bacillus which in cultures produced the characteristic odor noted above. This bacillus possesses active protolytic properties, at once suggesting its function in the wound, viz., the digestion of dead tissue; or, in other words, the destruction of the breeding ground of the pyogenic bacteria. Experiments on animals having proved that the anaerobe was nonpathogenic, at least to the animals employed, a wound which had been unsuccessfully treated with salt packs was inoculated with a living culture of the bacillus and again packed. The result was an entire success. In a short time the temperature fell, the foul odor developed, and a day or two after the removal of the packs the wound was clean. A number of further cases were tried, also with good results. In these it was found that the salt was an unnecessary part of the treatment. Wounds sewn up with the organism and packed tightly with sphagnum moss did equally well, suggesting that the salt bags merely acted by plugging tightly the wound and thus keeping it anaerobic. Dr. Donaldson has named his bacterium the Reading bacillus. Secretau looks upon secondary suture as one of the greatest advances made in wound treatment during the present war. It often shortens a man's convalescence by months, it perhaps allows us to convert a compound frac-

ture into a simple one—a thing of joy—and by diminishing scarring, it greatly simplifies any subsequent orthopedic operation that may be necessary.

Uniform Physical Standard to Govern All Examinations.—Uniform standards of physical examination governing the entrance to all branches of the armies of the United States for the use of all medical officers of the Army and of local and medical advisory boards under the selective service regulations have been published. It is believed that adherence to these new rules and regulations by the local boards will result in uniform examinations in all parts of the country and should prevent men physically disqualified for military service from being sent to camps. At the same time the new standards will enable local physicians to make examinations with a better understanding of the needs of the Army. These new standards are applicable to the Regular Army, National Army, and the National Guard. Explicit instructions are given as to what classes of men may be accepted pending treatment for remediable defects. Hitherto the standards of the three armies have differed and instances have been noted where men who have been rejected for service by the recruiting officer of the Regular Army have been accepted for military service by draft board physicians. Under the new standards this will not be possible unless the disqualifying defect be subsequently removed. The rule for all three armies is that to make a good soldier a man must be able to see well, have comparatively good hearing, his heart must be able to stand the stress of physical exertion, he must be intelligent enough to understand and execute military maneuvers, obey commands, and protect himself, and must be able to transport himself by walking as the exigencies of military life may demand. The exceptions made to this rule are in the case of men accepted for special and limited service.

Addition to Fox Hills Clearing Hospital.—The War Department has issued a statement showing that, under the Construction Division of the Army, a forty bed hospital ward was recently erected and ready for occupancy in 10 hours and 38 minutes. This building is an addition to the Fox Hills Clearing Hospital, known as General Hospital No. 10. The structure completed in this brief time is 156 feet in length, 24 feet wide, and has a porch running along one side of the building. During the course of the day nearly one thousand men worked on the building and by night the finished building was completely wired, the lights ready to be switched on, water running in the pipes, the radiators set, and fire extinguishers were hanging on the wall. The Construction Division of the Army is prepared for similar work in all the cantonments should the necessity for increased hospital facilities arise.

Safeguarding Health of Soldiers at Sea.—The Bureau of Medicine and Surgery of the Navy has a set of regulations for protecting the health of American soldiers on the transports going to France. Before embarking a thorough examination of troops is made by Army medical officers to eliminate the sick. Within five days of sailing the commanding officer of the troops submits to the senior naval surgeon a statement that all of his men have received protective vaccinations; if any have not those men are vaccinated. After embarkation all troops must spend at least an hour and a half daily on deck, each man bringing his blanket to be aired. Commanding officers must see that their men receive thirty minutes of physical exercise during this period. The men are expected to stay in the open as much as possible. All men and their effects must be inspected twice weekly by medical and commanding officers to detect the sick and make sure that the men are obeying the rules of hygiene. The men sleep "head and points" to prevent as far as possible the spread of infection by coughing. Every man has to take a shower bath daily and change his underclothing at least once during the voyage. Guards are stationed day and night at drinking fountains and other points to enforce cleanliness.

To Train College Students for Medical Corps Officers.—The Medical Department of the Army, through the National Research Council, expects shortly to issue an appeal to American Colleges and Universities urging them to alter their curriculum so that third and fourth year students may receive special training which will qualify them as officers and for other work in the Medical Department. The heads of all such institutions are requested to write to Dr. Richard M. Pearce of the National Research Council, Washington, or to the Division of Laboratories, office of the Surgeon General, for details of the proposed plan. The course proposed by the Medical Department should appeal to men who are specializing in biology, zoology, plant pathology, and agricultural bacteriology. After completing such courses arrangements for enlistment can be made through the Surgeon General's office if the applicant is under draft age, and if of draft age he can be inducted into the service and assigned where his special training will be of value. This plan has already been tried in two colleges and has been attended with such success that the Medical Department desires it applied to as many colleges as possible.

The National Association of Military Surgeons has received authority to hold its annual convention at Camp Greenleaf, on October 13, 14 and 15, 1918. An even more enthusiastic meeting is expected than that held at Fort Benjamin Harrison last year.

Surgeon-General Calls for More Nurses.—Surgeon-General Gorgas, on August 3, issued an urgent call to the American Red Cross to enroll 1,000 nurses a week for the next two months for immediate duty with the Army Nurse Corps. With the American armies entering more and more actively into the fighting overseas, Surgeon-General Gorgas says the need for more nurses has become imperative.

Campaign to Enroll Nurses.—The two weeks' campaign for the purpose of enrolling 25,000 volunteer nurses began on July 29. Surgeon-General Gorgas has written a letter to the heads of state committees on National Defense urging women between the ages of 19 and 35 to enlist before the campaign closes on August 11. He points out that the Army alone will require 25,000 nurses before January 1, 1919, and that about 13,000 of that number have been enrolled.

Dr. **William J. Condon** of New Brunswick, N. J., serving with the American Army in France, is reported wounded in action and undergoing treatment in a French hospital.

Technical Students Exempt from Draft.—Martin Conboy, Director of the Draft of New York City, has sent a notice to the local boards here announcing that students taking medical and technical courses in subjects considered essential to the conduct of the war be immediately placed in Class 5. These registrants must be attending a school recognized by the War Department's Educational Division. The order includes medical, engineering, chemical, physics, and certain technical students.

Massachusetts Doctors Get Special Call.—All physicians and surgeons in Massachusetts who are within the draft age and are in Class 1 have been ordered into military service. The registrants are to be inducted on August 11 and are to report at Fort Slocum, N. Y., where they will receive special training. These men are to be inducted regardless of whether they are physically fit for general or special service.

Influenza Among German Reserves.—A report from The Hague states that a special German correspondent writes that the pandemic influenza has attacked the troops held in reserve in Berlin and is having a very bad effect. It is said that underfeeding causes many attacks of the disease to end fatally that otherwise would have no such ill effect.

New Red Cross Hospitals.—Four new tuberculosis hospitals have been installed in Europe by the American Red Cross at a cost of $100,000. One of these is for the National Railway Union of France and another is for Serbian tuberculosis cases. A suggestion from the Army Medical Corps that a half-way hospital would be desirable close to the battle front in a certain section of France recently met with a ready response from the American Red Cross, which twenty-five days after the selection of a site had a 600 bed hospital ready for occupancy. The hospital is called a tent hospital, but is much more substantial than the name would indicate and has the advantage of being easily movable to meet the needs of the troops as they advance or retreat. The report of the American Red Cross for the month of July shows that, working in conjunction with many civil welfare agencies in France, 412,566 civilians have been aided during the month. During June seventeen civilian hospitals, having a total capacity of 1,698 beds, were opened in France. The society has also established 61 dispensaries in or near the war zone, where 45,028 women and children were cared for. The report shows that 45,000 refugees passing through Paris were aided during the month, immense quantities of food and clothing being distributed. There was a total increase, in June, of 85,000 civilians aided over the highest number for any previous month during the war.

Hospitals Ask the Government to Cooperate.—A special meeting of the War Committee of the American Hospital Association was held in the New York Academy on June 3, to consider ways and means of meeting the shortage of physicians and nurses in the civilian hospitals. After the serious situation confronting the hospitals was set forth, the following resolutions were adopted: "Resolved, That under the direction of the Federal Health Administrator or other suitable Federal authorities, a program should be prepared for maintaining an adequate supply of medical students and properly trained physicians during the war. In so far as the extension of the existing facilities for training may become necessary the means for such extension should be provided by the Government. Surveys in medical and nursing fields which have already been undertaken by the Governmental and private agencies should be extended, coordinated and completed. A program should be prepared and carried out in cooperation with the military authorities for the most effective disposition of students of medicine who are of draft age and for the modification of their training to meet war requirements. Medical institutions, physicians and nurses should be brought under the direction of the Government whenever necessary to secure adequate attention to the needs of the civilian population. A resolution was also passed asking the Red Cross Relief Commission to investigate the shortage of hospital personnel and to report what could be done to help institutions compelled to compete with the Government in the matter of salaries.

New United States Ambulance Ship.—The former Ward liner *Saratoga* has been fitted up to serve as an ambulance ship between this country and the American naval base abroad. The ship has been renamed the *Comfort*. It is the first American hospital ship to enter the war zone. The present plans are to send the ship unconvoyed, notifying the German Government of the ship's intended voyage and its purpose. The vessel will bear all the distinguishing marks prescribed by the Geneva convention. It seems like a foolhardy undertaking to trust to the honor of Germany, for that country has shown by its sinking of English hospital ships and its bombing of our hospitals and those of our Allies that it has forgotten, if it ever knew, the meaning of that word.

Hospital Provisions for American Soldiers in Paris.—The American Red Cross has provided 3,000 beds for American soldiers in the Paris district and 1,000 more will soon be ready.

Red Cross Supplies Stolen.—An organized syndicate has been systematically stealing goods from the Red Cross in Boston for some time past. It is said that thousands of dollars' worth of goods have been taken from trucks during the driver's absence. Huge stocks of supplies have been found in the shops and homes of three cobblers, who were recently arraigned in the Dorchester District Court on the charge of stealing these supplies.

Army Dentists.—Speaking at the annual meeting of the National Dental Association in Chicago on August 6, Surgeon-General Gorgas said that the work of the army dentists was of double value. "In the first place, they help to keep the general health of the army up to a high standard, and, in addition, the dentists are doing wonderful work in reconstructing the faces of soldiers who have received head wounds from shrapnel."

Lieutenant-Colonel Mortimer Sanderson, Medical Corps, U. S. Army, died at Camp Cody, Deming, N. M., from mastoiditis, on August 1, aged 32 years. He saw service in the Philippines and on the Mexican border.

MEDICAL RECORD.

New York, August 10, 1918.

THE INFANTILE PARALYSIS CONTROVERSY.

THE rational prophylaxis and therapeusis of an infectious disease rest chiefly on the identification of its specific etiology. In this connection one only has to cite the wonderful results obtained from prophylactic inoculation against typhoid fever and the antitoxin treatment of diphtheria. Without knowledge of the microbic causes of these two diseases, preventive measures in the first-named infection and curative measures in the second could never have been developed to the high degree of efficiency which they have attained. The infantile paralysis situation has not yet reached this desirable level, due probably to the technical difficulties encountered in working with the etiological factor, which is believed to be in the nature of a filterable virus, a far more intangible agent to handle than the readily demonstrable typhoid or diphtheria bacillus. The globoid bodies originally described by Flexner and Noguchi are now regarded by the majority of investigators as the cause of the infection. Some students of the disease, notably Rosenow, claim that certain forms of streptococci play an etiological role. In fact, he and his coworkers go so far as to state that the streptococci which they isolated from the cerebrospinal fluid and tissues of poliomyelitic cases are biologically related to the globoid bodies. This statement has been disputed by Amoss and Eberson, who positively affirm that streptococci are in no way akin to the globoid bodies, and, what is more important, that they are of no etiological significance.

As a result of this difference of opinion in respect to causation of the disease, it is evident that the problem of specific therapy and prophylaxis offers two contingent means of attack based on immunological grounds. One group has employed serum from convalescent and recovered cases of infantile paralysis in the treatment of the infection, with favorable results. On the other hand, Rosenow, working on the basis of a streptococcus etiology, claimed considerable success from the use of a serum prepared by immunizing horses against streptococci isolated from poliomyelitic cases. Amoss and Eberson point out (*Jour. Exper. Med.*, Feb., 1918) the well-known fallacy of drawing conclusions from a small group of cases, and assert, in order to arrive at a decision from the treatment of human patients, a large and varied series of observations would be required extending over a long period of time and embracing epidemics of wide magnitude and various degrees of severity. These workers were able to demonstrate experimentally that Rosenow's conclusions are based on incorrect premises. In the first place, they tested the ability of the immune streptococcus serum to prevent a poliomyelitic infection arising in a monkey after an intravenous injection of the virus. Secondly, they compared this serum with the serum of immune monkeys as regards the antibody content. They were able to show conclusively that Rosenow's serum is ineffective therapeutically in monkeys, and does not possess antibodies of the same nature as those present in the blood of animals which have recovered from poliomyelitis. Since the antibodies in man and the monkey are identical, it follows that any antibodies in the immune horse serum do not conform to those occurring in convalescent human patients. The logical deduction to be drawn from this reasoning is that streptococci are not the cause of infantile paralysis. The weight of evidence is certainly against the possibility of any such pleomorphism of the organism as contended by Rosenow. It is therefore safe to say that the relation of the globoid bodies to the etiology of the infection remains unimpeached. Beneficial results purporting to be derived from the injection of antistreptococcic horse serum cannot be attributed to any specific action on the part of the serum. It is highly probable that the streptococci which have been found in cases of poliomyelitis by various investigators are secondary invaders of a host already infected with the true virus of the disease.

THE SUPERSTITIOUS SURGEON.

SOME say that the all-around practitioner who treated typhoid, set broken bones, operated on hernias, prescribed glasses, and even in a pinch pulled teeth, is becoming a tradition only. Except in the most sparsely settled regions of our country his place has been taken by the internist, the surgeon, the ophthalmologist, the dentist, the orthopedist, *et id omne genus*. And of all these specialists the surgeon is the most superstitious. Let us inquire into this. The family physician usually knows his patient from his grandfather down to his children. He is aware of the family tendency towards stoutness, their idiosyncrasies for cabbage or quinine. When called upon to treat them he does so with one eye on their symptoms and the other on the family chart. He can predict almost exactly how long and how severely they will be ill and how quickly they will convalesce.

But the surgeon of to-day has no such special knowledge. He is summoned, we will say, to see a patient with appendicitis. He arranges for an operation that afternoon at four and hurries away.

He operates, perhaps he dresses the wound once or twice and it may be removes some stitches and then never sees the patient again. Nowadays, of course, infections are rare. But occasionally one does occur inexplicably. Then the surgeon is blamed, the patient and his friends are alarmed, and a little ripple of disrepute goes out to do who knows what harm to the operator's standing. The surgeon prepares himself in the same way for every operation, neglecting no detail. But when he steps into the operating room and takes his scalpel and forceps he is in the realm of chance. A mistake by his assistant, a slip by the clean nurse, one little germ wiggling through the circumambient atmosphere may nullify all his labor and skill. One little deviation of his knife and an artery or gut is cut, doubling the labor and prejudicing the result. Too much handling of the intestines and shock follows; too little and some important condition is overlooked. A drop of pus escapes from the protecting gauze: peritonitis and death; the assistant makes a mistake of one in counting the sponges: a law-suit and heavy damages. And with it all, beyond all the eventualities which can be traced as attributable to human fallibility, there are those cases which do badly for no discernible reason. The big, healthy looking man comes to the surgeon for an interval appendectomy; it is a clean operation and everything goes smoothly for two or three days. Then his pulse goes up, he begins to sink, and dies. Or ether pneumonia supervenes in spite of the expert anesthetist and perfect post-operative care.

Small wonder then that the surgeon gets to believe in the Goddess of Chance. He has his lucky and unlucky days. He does his part with the unerring skill of which he is master. The rest is on the knees of the gods. We know surgeons who will not operate on Friday, who must wear a certain gown, who will not let a red-headed nurse assist them, who will postpone an operation until the next day because they have spilled salt, who must be the last one in the operating room and so on. We all know these and many others. It is no reflection on their skill, but rather an indication of the immense complication and subtleties of the human organism.

During the Civil War out of every 100 wounds 99 became infected and one inexplicably remained free from "laudable pus." Now 99 wounds are clean and one becomes mysteriously infected. In 1950 perhaps infection following any kind of operation will be so rare as to be reported at length. Thus the domain of the unknown is shrinking and medicine may one day take its place among the exact sciences, with no place for chance or superstition.

ANTHRAX FROM SHAVING BRUSHES.

Few diseases are more deadly than anthrax of the malignant pustular type. Fortunately, the infection has been almost as rare as it was fatal owing in part to the low human susceptibility to anthrax and in part to the extreme care taken to disinfect any material in which the germs of the disease might lurk. The most common form of anthrax is the pulmonary or woolsorter's disease; an internal type, to which, as its name amplies, woolsorters are prone when engaged in sorting infected wool. This form is contracted by inhalation of dust containing *Bacillus anthracis*. The most fatal type of the infection is the malignant pustular or malignant edematous, the cutaneous form of anthrax. Recently in this country, several cases of anthrax, apparently due to infected shaving brushes, have been reported to the Public Health Service by the Surgeon General of the Army, and were commented upon in Public Health Reports, July 12, 1918. In Great Britain, during the past three years rather numerous cases, considering the rarity of the disease, have occurred, and a proportion of these have been directly traced to the use of infected shaving brushes. Some of these cases were in civilians, but more among soldiers. Among the British troops in France, there were 28 cases of anthrax from January, 1915, to February, 1917, but although the circumstances strongly pointed to infected shaving brushes as the cause conclusive proof was lacking. From the beginning of the war up to February, 1917, 18 infections with anthrax occurred among the troops in Great Britain, 12 of which were on the shaving area, while four were almost certainly due to shaving brushes.

The British experience is contained in Local Government Board Reports. There were 33 cases of which the outcome was known; 21 of these died, a mortality of 64 per cent. According to the report of R. G. H. Coutts, the case mortality probably appears higher, because it is likely that many mild cases recover without diagnosis. However, there is little doubt that this form of anthrax gives a high mortality; an explanation of this possibly rests in the site, infections of the neck being more serious than those on other parts of the body. It may be said that meningitis due to the anthrax bacillus has been reported from Holland and Great Britain, and one of the recent American cases has been of this type.

As for the kind of brushes to which infection was traced, it is stated in Public Health Reports that 15 of the civilian cases were due to 12 different kinds of brush, 6 of them from one manufacturer. It is, moreover, stated that some of the infected brushes were made from hair which had presumably been disinfected in accordance with requirements. Horsehair from China and Siberia seemed to be that principally involved, and the use of such hair, in ordinary circumstances regarded with suspicion by manufacturers, was owing to the letting down of the bars on the part of the older manufacturers and carelessness on the part of new manufacturers who knew little of the danger of horsehair. With regard to disinfection it appears that black or thoroughly dyed hair was disinfected satisfactorily,

but that there is a tendency to avoid high temperatures in the disinfection of the white hair and of that colored to imitate badger hair.

Now that it is known that shaving brushes infected with the *Bacillus anthracis* are in this country, it is obvious that greater care must be displayed in the selection, inspection, and disinfection of cheap brushes. Possibly, it would be in the best interests of the public health if brushes made from Siberian or Chinese horsehair were not allowed entry into the country and, in any event, such hair should be thoroughly disinfected.

Effects of Shell Explosions.

In the *Archives médicales belges* for June, Hoven gives a summary of our knowledge of this subject as gleaned from a number of first hand reporters. The type of injury considered is limited to commotion of the nerve centres. The proximity is an essential factor, and experience shows that explosions at any distance from one to ten meters may give rise to the same symptoms. The projectiles are of the type commonly spoken of as large, but no exact dimensions are given. The results of commotion are extremely complex. As a rule there is a neuropathic predisposition, but this is not necessarily inherited; it may be acquired as a result of various experiences, especially depression and weakness as a result of military life and hardships. Immediately after the explosion and consequently on the battlefield the commotion may be expressed as coma, or as confusion attended by amnesia. Other subjects show emotional behavior. The more remote disturbances may be nervous or mental. Under the former we may encounter organic manifestations such as paraplegia, the cord showing the greater predisposition. Under mental manifestations we may see acute stuporous or hallucinatory confusion. The prognosis of affections having an organic basis is bad for recovery. In all of the other results of commotion the outlook is favorable. That is to say, the immediate results are good, but sequelæ may supervene after apparent recovery. These sequelæ may be nervous or mental. We may see a hyperemotive syndrome or intellectual disturbances. These late phenomena are of great importance. In certain cases the mental troubles go on to form a psychosis with terminal dementia. The pathogeny of these affections is not understood and at present we have only theories to offer. Only in certain cases do we see organic alterations such as hemorrhage and areas of softening.

Treatment of Epithelioma.

The success which has recently attended the treatment of cutaneous leishmaniosis and other disfiguring processes in tropical regions with antimony appears to have stimulated a research into the subject of the amenability of epithelioma to the same principles of management. Some remarkable cures of noncancerous maladies with a combination of arsenic, antimony, methylene blue, and other substances have influenced De Rezende to test the same formula in epithelioma of the skin. In the *Brazil-Medico* for May 11 he relates that a patient aged 58 years applied to him with a destructive lesion of the left ala nasi. The duration of the malady was 6 years, and after a partial operation the mixture was applied and the ulcerated area promptly cicatrized. In 8 or 10 months a local recurrence was in evidence. The mixture was again applied with the same good result. In the past three years the author has treated in all five cases of epithelioma of the face with his mixture, and in all of the cases has obtained complete recoveries. He seems to have made no effort as yet to simplify his formula, which is somewhat unwieldly, since it contains 10 active substances which are supposed to behave as synergists. These comprise arsenous acid, copper sulphate, methylene blue, methylene violet, quinine bichloride, tartar emetic, camphor, menthol, phenol, and antipyrin. The four last named, in addition to other properties, are all analgesic.

News of the Week.

Big Mills Establish Day Nurseries.—Day nurseries for the care of the younger children of the women employees will be established at the Washington and Wood mills of the American Woolen Company at Lawrence, Mass. The nurseries will be conducted on the group system, one group for the care of very small babies, the next for children from one and one-half to three years, and the third for children from three to five years of age.

Mosquitos Exterminated from Hog Island.—Officials of the United States Shipping Board state that they believe that Hog Island, now the center of a vast ship building industry, is effectually rid of mosquitos. The work involved the draining of a marsh twenty-five miles long at a cost of $250,000. New Jersey has been reluctant to take such steps, but since witnessing this achievement it has been decided to expend $150,000 to drain the Newark meadows near the Submarine Boat Corporation Plant and has instituted work at the Camden yards across the river from Hog Island.

Bacillary Dysentery in Poughkeepsie.—A few cases of bacillary dysentery have again appeared in Poughkeepsie, where the disease has been epidemic during the past two summers. In each instance it has been found that the cases occurring this summer are in families which had the disease last summer. Two persons who were ill with the disease last summer have been found to be carriers.

Hookworm Disease Diagnosed by State Laboratory.—Among the unusual diagnoses recently made by the laboratory of the State Department of Health is a case of hookworm disease in a patient who recently came to this State from the South.

Lake George Health District.—The shores of Lake George have been converted into one health district by an act of the Legislature. This district takes in all the territory bordering on the lake and includes practically the entire watershed, comprising nine towns situated in three different counties. Prior to the creation of the district it was possible for one municipality to nullify to a large extent any attempt at improved sanitary conditions on the part of its neighbors. This difficulty will now

be overcome. The act of the Legislature provides for a full time health officer and a sufficient appropriation to carry on the work in an efficient manner. It is believed that the results obtained under these conditions will justify the creation of similar health districts in other parts of the State. Dr. Minna R. Rohn has been given charge of the district.

Memorial to Dr. Edward A. Trudeau.—A statue, the gift of former patients of the Adirondack Cottage Sanatorium, at Saranac, in memory of Dr. Edward A. Trudeau, will be unveiled on August 10. The memorial address will be made by the Rev. Philemon F. Sturgis.

Dr. William C. Woodward, formerly of the United States Public Health Service, assumed his duties as health officer of Boston on August 1. One of his first tasks is an investigation in conjunction with the mayor's tenement house commission having as its aim the betterment of living conditions in Boston.

Dr. Samuel T. Darling of the International Health Board has been appointed professor of hygiene and director of the laboratories of the Faculdade de Medicina e Cirurgia of Sao Paulo, Brazil.

Dr. Benjamin Mann has been appointed assistant medical inspector in the Philadelphia Bureau of Health.

Dr. J. Torrance Rugh has been elected professor of orthopedic surgery in Jefferson Medical College.

Dr. Elliott Dorn, formerly resident physician and roentgenologist at the New York City Municipal Sanatorium at Otisville, has been appointed superintendent of the "Pleasant Valley Sanatorium," the new Steuben County Tuberculosis Hospital.

Dr. Ernest I. Werber, a German student who has been engaged in research work at Yale University, has been interned in a camp in Utah for the period of the war. The authorities of Yale University have issued a statement saying that the laboratories will for the duration of the war be closed to all but those engaged in work for this Government.

Donations of East River Home Foundation.—The East River Home Foundation of New York City makes the following donations from its net income from the past year: tuberculosis work of the Vanderbilt Clinic and Presbyterian Hospital tuberculosis clinic, each $9,000; civilian tuberculosis relief work in France, under the direction of the American Red Cross, $8,000; the Trudeau Sanatorium, Saranac Lake, and the Loomis Sanatorium, each $3,000; the New York Association for Improving the Condition of the Poor, $2,500; the Stony Wold Sanatorium for the tuberculosis league work, Lake Kushaqua, N. Y., $1,000; the Hospital and House of Rest for Consumptives, Inwood, N. Y., $1,000, and the Henry Street Settlement for tuberculosis nursing, New York City, $500.

The National Medical Association will hold its twentieth annual convention in Richmond, Va., on August 27, 28 and 29, 1918. Surgical clinics will be held at the Richmond Hospital; medical clinics will be held in conjunction with the regular program; motion picture clinics will be held in practical dentistry, and pharmaceutical demonstrations have been arranged. For further information address, Dr. W. G. Alexander, 14 Webster Place, Orange, N. J.

The Montana Medical Association, at its annual meeting held in Butte, on July 11 and 12, elected the following officers: *President,* Dr. E. W. Spottswood of Missoula; *Vice-Presidents,* Dr. C. C. Wallin of Lewistown, Dr. A. R. Varco of Miles City, Dr. A. Karsted of Butte; *Secretary-Treasurer,* Dr. E. G. Balsam of Billings.

Charitable Bequests.—By the will of the late Samuel B. Vrooman of Philadelphia a memorial trust fund of $3,000 is bequeathed to the Lankenau Hospital.

By the will of the late Clara B. Miles of Philadelphia bequests are made as follows: Children's Aid Society and Samaritan Hospital each $2,500; and residuary bequests of $5,000 each to the Home of Our Merciful Saviour for Crippled Children and the Protestant Episcopal City Mission, for the Hospital for Diseases of the Lungs at Chestnut Hill.

By the will of the late Sarah A. C. Lloyd bequests of $25,000 each are made to the Children's Country Week Association, the Children's Aid Society, the Children's Homeopathic Hospital and the Women's Homeopathic Association of Pennsylvania.

Obituary Notes.—Dr. FORBES J. MUNSON died at his home in Brooklyn, N. Y., on July 27, aged 49 years. He was a graduate of the Long Island College Hospital, in 1897, and for more than twenty years a diagnostician of the Department of Health.

CAPTAIN HENRY BURT HERRICK, M.R.C., of Cleveland, Ohio, died suddenly at Brest, France, on June 16, where he was buried with military honors. He was a graduate of the Western Reserve Medical Department in 1891 and was 55 years of age.

Dr. CHARLES WALTON SANDERS, a graduate of the College of Physicians and Surgeons, New York, in 1878, died at his home in New York City, on July 22, aged 72 years.

Dr. WILLIAM A. GILLEN, a graduate of the College of Physicians and Surgeons, New York, in 1906, died of typhoid fever at his home in Brooklyn, on July 29, aged 35 years. He was assistant attending surgeon of St. Mary's Hospital.

Dr. JOSEPH M. CREAMER of New York died at his summer home at Deal, N. J., on July 28, aged 48 years. He was a graduate of the Long Island College Hospital, in 1897.

Dr. HENRY M. LEWIS of New York, a graduate of the Hahnemann Medical College, New York, in 1870, died on July 28, aged 69 years.

Dr. JOHN J. A. DOYLE died at Philadelphia, on July 6, at the age of 43 years. He was graduated from Jefferson Medical College in the class of 1897.

Dr. CHARLES R. F. GREENE, a graduate of the New York Homeopathic Hospital, in 1892, died suddenly at his home in Peekskill, N. Y., on August 1, aged 50 years.

Dr. THADDEUS M. ROHRER died at Quarryville, Pa., on July 30, at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1881. He was for four terms Burgess. He was a member of the Lancaster County Medical Society, the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Correspondence.

THE UNEXPIRED LEASE AND THE UNPATRIOTIC LANDLORD.

To the Editor of the Medical Record:

Sir:—Let me call attention to the following extract from a letter received recently from a captain in the Medical Reserve Corps, U. S. Army, a former practitioner in New York City, now stationed at one of the remote Southern training camps. He says: "They talk about how grand it is for the doctors to give up their practices, but no one seems to think of making things easier for them at home. For instance, I am held for the lease of my office and as far as I can ascertain they intend to hold me to it. By the time I have paid rent, storage, and insurance I have thirty dollars a month left, which is more than taken up by the thirty-five dollars a month for mess, laundry, etc." The writer of the above has given up safety, comfort, and an excellent practice for motives of highest patriotism. Doubtless his case is not unusual, for it appears that many landlords are holding to their contracts men called from civil life to active military and naval service.

The distressing nature of this hardship is evident. I understand that the question has recently been brought before Congress. Is it not possible to devise some method of relief?

D. Bryson Delavan, M.D.

New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

NOTIFIABLE INFECTIOUS DISEASE DURING 1917—DEATH OF SIR JAMES MACCULLAGH—THE PHYSIQUE OF AMERICAN SOLDIERS—THE GALLANTRY OF THE R. A. M. C.—THE EPIDEMIC OF INFLUENZA—THE LONDON FOOD SUPPLY—MEDICAL CORONERS AND CORONERS' JURIES.

London, July 11, 1918.

The principal medical officer of the Local Government Board has issued a report on the local incidence of notifiable infectious disease in England and Wales during 1917, and the ten months which have elapsed since the completion of this period were fully wanted for the proper preparation of a document dealing with such a multiplicity of figures. One remarkable statement deserves particular comment—only seven cases of smallpox were reported during the year, whereas the average number of cases reported in the previous six years was twenty times as high, namely 140. The immunity of these islands from smallpox is becoming a very gratifying feature of local medical administration. When in April last a smart little epidemic of smallpox broke out in the East and riverine districts of London, there was considerable apprehension of a rapid spread. The localities affected were crowded, and were also the favorite target of enemy air-raids, with the result that the populations were constantly intermixed in the closest manner in bomb-shelters and tube-railways. But those who knew how effectively the sanitary organization of the local government board did its work did not share these anxieties and their optimistic outlook was justified, for "the plague was stayed" in a few days. These cases, however, will restore the smallpox figure in these reports to its average. The only diseases which showed an increased prevalence during 1917 were pulmonary tuberculosis and cerebrospinal fever, but the tuberculosis figure has not gone up by any horrifying amount, being 73,654, as against 72,479 last year. The increase is not so high as was expected, having regard to the possibility of the spread of infection by returned troops. The cases of cerebrospinal fever notified to the health authorities amounted to 1,465 against an average of 1,123 in the previous four years—earlier than that date the cases were not notified. Scarlet fever showed a drop of over 50 per cent., with 45,000 cases notified, while substantial reduction in cases is recorded with regard to typhoid fever and diphtheria. The report is the seventh in succession to be issued from the Local Government Board, and as the series grows longer the more obvious does its utility become as a record of the past from which the sanitary and health policies of the future can be constructed.

The death of Sir James Acheson Maccullagh of the medical staff of the Local Government Board for Ireland, took place last week at Roscommon with tragic suddenness. He was conducting an inspection in his very trying district of Western Ireland when he fell down dead while engaged in conversation. Sir James Maccullagh was a very competent official and sound epidemiologist, but he obtained his knighthood rather for his political services as mayor of Derry than for his scientific achievements.

For some weeks now the streets and railway stations and general places of resort of London in particular, but also of all the other large cities directly connected with the organization for war, have been regularly thronged with American soldiers; for although the bulk of the American Expeditionary Force has been placed upon French soil direct in the extraordinarily gratifying circumstances which were the subject of a recent official pronouncement, a large number in the aggregate have visited England. The common verdict upon the physique of these American soldiers is one that must be highly satisfactory and gratifying to our great English-speaking ally. Medical man after medical man has commented with approval and even admiration on the appearance of the American soldier, his alertness, activity, adaptability, and cheerfulness. To the eye of the medical man with large military experience the American soldier does not conform to the type of the highly finished material which fills the Guards regiments, the Royal Marine Light Infantry, or the Rifle Brigade, for example; but on the one hand the absence of this high finish and demeanor can be no possible drawback for actual service, and on the other, a certain proportion of the American troops whom we see on our streets are receiving the last stages of their training, although so many thousands are now in the fighting line. The medical views on the material of the American Army are extremely cheering, for there is a notable absence among the American soldiers of the kind of defects which are aggravated by the exigencies of war, and there seems no doubt

that the ordinary life of the industrial and commercial population of the United States is carried on under more hygienic conditions than it is carried on in this country. This is a very important matter at the juncture of the war which we have now reached, for time is becoming a factor of the first importance. Thousands upon thousands of English soldiers have gradually been toughened by their experiences and present now a physical makeup which renders them impervious to many ills which at the time of their recruiting would have laid them up. While this is very comforting knowledge—especially comforting as it may be taken in some measure to counterbalance the knowledge that the wastage from disease has been high, it has to be remembered that this "salting" of the British Army is a process which has taken two or three years to develop. It would be an anxious situation if the American Army had to wait so long before it was fighting at top strength, and it is therefore particularly cheering to think that in medical opinion our Western Allies have arrived in Europe ready for the great struggle in which they have already begun to cooperate with conspicuous success.

The latest list of honors and decorations awarded for gallant behavior in the field includes a large number of medical names, and should effectively prove to the public mind that the division of the troops into two categories—combatant and non-combatant—and the relegation of the Royal Army Medical Corps to the latter division is a wholly artificial arrangement. Nowadays, on the immense fighting fronts there are no "non-combatants." Every one in an active zone is under fire from far-ranging guns or aerial machines, and at any moment a particular sector of the line, by concentration of enemy activity, may be involved for miles back in the fiercest forms of combat. It is only two months since I commented upon the fact that the latest official Gazette contained the details of the heroic actions performed by no less than 96 medical officers serving with the British Navy and Army. The accounts are now published of the gallant behavior which has led to the decoration of 53 officers, all members of the Royal Army Medical Corps, of whom 44 have received the Military Cross, 6 the bar to the Military Cross, 2 the Distinguished Service Order, and 1 the bar to the Distinguished Service Order. The exploits of Colonel Arthur Carr Osburn, the winner of the last-named and very rare distinction, are thus officially set out: For conspicuous gallantry and devotion to duty. On seeing the enemy approaching close to his dressing station, he carried out the evacuation of the wounded under heavy shell and rifle-fire in the coolest and most gallant manner. Having cleared away all cases by ambulance train and cars, he restablished his dressing station further in the rear. As officer commanding a bearer division he constantly inspected his line of bearer-posts and forward dressing stations under heavy fire. The successful evacuation of the wounded from the divisional front was due to his careful organization and fearless supervision under the most trying conditions. His was an example of gallantry, courage, and resource worthy of the highest praise.

There is clearly nothing "non-combatant" about services of this kind; on the contrary, military routine and resourcefulness were alike employed by Colonel Osburn in circumstances of the greatest possible difficulty and danger.

The epidemic which has fallen with considerable rapidity on all classes of our population, civil and military, shows as yet little signs of dying out. It has now been apparently promoted to a name and is definitely termed "influenza," although a good many cautious authorities consider that there is no proof that many of the cases are influenza. The clinical features, as they have appeared in England, match very well with those of the first cases in Spain and the South of France, and also resemble the cases which we know to have broken out in the Bavarian army. Headache, pain in the back, nasal and pharyngeal catarrh, and a high temperature for 48 hours are the usual symptoms. Invasion of the respiratory tract is not common, though a certain number of deaths from pneumonia have been recorded; but in addition to the pulmonary type of the disease there is a malignant type, where the onset is sudden, where coma and delirium supervene rapidly and where death takes place within 24 hours. One reason why the widely spread epidemic is not universally accepted as influenza is the absence of the bacillus influenzæ from the exudate in the upper air passages. Attacks of so-called influenza are often due to other organisms than the *Bacillus influenzæ*, but on the other hand it is a little against the scientific grain to label the disease influenza when Pfeiffer's bacillus is frequently absent. Serious bacteriological study of the pandemic has however now begun, with the probability that its epidemiology may become clearer.

The starvation of England by the German submarines never for a moment looked like a possibility, but it is a curious thing that London, the capital of the Empire, should have suffered from the restricted food supply more than any other city or district. At any rate, this is a proof that rationing was conducted on democratic lines, for it was the wealthiest center that was the worst served. London was the only great city where medical men had difficulty in obtaining those extras which certain patients require when fighting against injury or disease. And even now, with the U-boat menace a thing of the past, it is in London where the excessive prices, produced by the dread of scarcity, rose to the highest point and where these prices have most conspicuously failed to descend. National restaurants and national kitchens are selling meals at half the prices demanded in restaurants and by caterers, and medical men, whose patients are going short in their homes and in nursing institutions, are beginning to think that there should be a limitation to the profits of purveyors.

A generation ago it was a perpetual subject of discussion in medical and legal circles as to whether the coroner should be a lawyer or a medical man. There is nothing in any British Act of Parliament which makes it necessary that a coroner should be of either profession, but from the sixteenth century onward the office fell regularly into the hands of the legal profession. The in-

quiries might, in many instances, be of great criminal importance and it was considered to be safer for the community that such inquiries should be conducted by lawyers rather than by those unfamiliar with legal formalities.

This view was rudely challenged in London nearly 100 years ago, where a strong feeling became manifested, owing to the conduct of certain coroners' inquests, that the right person to preside over an inquiry into the causes of sudden death was a doctor and not a lawyer. One of the chief champions of this view was Thomas Wakley, Member of Parliament for Finsbury and editor and founder of *The Lancet*, who became one of the coroners for the metropolis, and in many large towns the precedent was followed, medical men being elected to preside over these courts of first instance. A reaction against the tendency in the important centers to appoint doctors as coroners was caused by the celebrated Bravo case in 1876. Bravo, a wealthy barrister, died of a dose of tartar emetic, how and when administered never being discovered. There were two inquests at which an enormous amount of irrelevant evidence was admitted and at which the real problems were never elucidated. The coroner was not a lawyer, and it was wrongfully assumed that he was therefore a medical man, but he seems to have belonged to neither profession. The impression left on the public mind, however, was that the coroner's inquest was a legal inquiry, and that the ends of justice might be defeated if a lawyer did not preside over the court. This view has gradually waned, and a reaction in the big cities toward the appointment of medical men has taken place, but most medical men consider the coroner's jury to be to-day a complete anachronism. Of what use can it be to explain pathological details to a tribunal of so low a standard of education? Medical men would probably prefer that the post of coroner should be held by a lawyer, with whom there should sit, as medical assessor, a physician to advise the court as the bearing of the medical evidence given; the court delivering the verdict without the hampering assistance of an ignorant jury.

OUR LETTER FROM PARIS

(From Our Own Correspondent.)

AMERICAN HOME FOR SOLDIERS IN PARIS—CIVIL WORK OF THE RED CROSS FOR MARCH—PROFITABLE WORK FOR THE BLIND.

PARIS, June 25, 1918.

THE American Home Service for soldiers and sailors abroad is increasing its activities daily, and Mrs. Weeks is taking a new Paris home for them and also a beautiful big villa at Aix-les-Bains, where they are to have every comfort. The new Paris home is located at 21 Avenue des Champs Elysées. The apartment is more spacious than the present quarters and being near the new Headquarters of the army, the soldiers will probably find it more convenient. In the new, as in the present quarters, tea will be served every afternoon free of charge. There will be lounging and writing rooms and a few bedrooms, where those who come to Paris for a night or two can have accommodations for a few francs. There will also be a complete library containing good books and magazines, and above all there will be that personal touch about the place that only a mother can give, and especially a mother who once administered to the wants of a son who gave his life for France. The branch which has been opened at Aix-les-Bains will serve the men on leave in the same way. Mrs. Harris has charge of the work there, and will be assisted by some of the American girls who have helped Mrs. Weeks in Paris.

The Home Service is becoming widely known among the soldiers, and Mrs. Weeks says that recently the results of the work are beginning to show in the letters which she has been receiving from the men. The name of each man is put on file and all of the details about him, even down to his personal experiences at the front about which he has written, so that any information can be communicated to his relatives in America in case the soldier himself is unable to write. After May 15 American soldiers in Paris are invited to make themselves at home in the new quarters at 21 Avenue des Champs Elysées.

The March report of the Civil Affairs Department of the American Red Cross contains highly interesting facts and figures regarding the aid given to refugees and soldiers in the first phases of the present German offensive. The number of persons aided is shown to be surprisingly great. Food, clothing, transportation, or shelter was given to 23,479 refugees during the offensive in March, while food was given to 83,000 French and American soldiers served in emergency canteens. The remainder of the report shows a vast increase in the work of the Civil Affairs Department throughout France. Work is being carried on in 121 cities and villages, without counting nine temporary emergency stations for refugees' work in the war zone and two temporary emergency hospitals. There are eight civilian hospitals, with a total of 1,051 beds, and forty dispensaries giving medical care to tuberculous refugee children, and 1,500 children refugees from the war zone are being housed and given medical care in three refugee homes. The refugee work has been extended to twelve new departments, so that seventy-one delegates and associates are now covering fifty-eight departments in France in the care of repatriated and refugees outside of the war zone. During March, 16,956 persons, of whom 12,000 were children, received medical care in hospitals and dispensaries. Medical relief was given altogether to 106,480 persons, of whom 51,000 were children, and 4,849 refugees were housed. These figures do not include the refugees and soldiers who received aid in the recent German offensive.

The farm for the re-education yearly of 300 French war cripples was organized in March. Thirty thousand Paris school children received supplementary food for déjeuner during March. Employment in other services was found for 5,554 refugees, making a total of 168,318 civilians aided during the month. Sixty-six thousand of these were children, 10,141 tuberculous, and 84,777 refugees, including children and residents of the war zone, and 8,500 French war cripples. The increase over February in the number of civilians aided is 65,344, or 63 per cent.

The money donations to outside organizations during March totaled 391,802 francs, of which 57,915 francs went to the tuberculous, 222,209 francs to refugees, 27,850 francs to reconstruction and relief of the devastated area, 31,503 francs to children, and 52,802 francs to war cripples. The goods distributed by all bureaus through delegates included 119,149 garments, 11,998 pairs of shoes, 79,716 articles of furniture and household utensils, 67,326 articles of bedding and household linen, 35,100 yards of cloth, 362,463 pounds of food, 3,420 articles of hospital equipment and supply, 955 tons of coal, 2,947 agricultural implements, and 11,471 miscellaneous articles. The staff of the Civil Affairs Department on April 1st numbered 738, of whom 75 were physicians and 121 nurses.

Soldiers of France blinded in the war are to be given an opportunity of earning their living in the electrical industry through the generosity of the Thomson-Houston Company, whose president, M. Charles Laurent, yesterday notified all interested organizations of the scheme. In his letter, which was sent to all the societies and hospitals associated with the reeducation and care of blinded soldiers, M. Laurent says, in part: Desirous of assisting our country by providing employment for the soldiers of France who have been blinded in battle we have decided to establish workrooms for them, where they will be able to earn a good living winding armatures for motors after the system introduced by Dr. Schuyler S. Wheeler of New York, who has successfully employed a large number of American blind in this work. It has been demonstrated that the blind are especially adapted to this work, owing to their sensitive and skilful fingers. The work is not arduous and is easily learned. There is also plenty of it, and the blinded soldier can rest assured that he can work at it when and as long as he likes. The work is paid for by the piece; that is, according to the amount of work done, so as to leave the soldier complete freedom of action. In its first stages this work consists of insulating the coils used in building up the armatures for motors and dynamos. The primary insulation is done by winding the bare coils with various kinds of tapes. Dr. Wheeler yesterday gave a brief description of his experience with the blind in this work, which was started by him less than a year ago, at the electrical factory of the Crocker Wheeler Company in Ampère, N. J., of which he is president.

The blind learn easily and quickly and after a few weeks are very little slower than the others. In this work the blinded soldiers of France will be able to become independent and earn their own living without the help of charity. The demand for their product will always exceed the supply, and they will always find a ready market for their coils. It is proposed to start this work for the English blinded soldiers, and Dr. Wheeler is going to England this week for the purpose. He has successfully demonstrated that it can be done by the French blinded soldiers. On his return to the United States, he will greatly enlarge the scope of the electrical work now done by the American blind. Dr. Wheeler's projects include close cooperation between France, England, and the United States, and every new development in this work that is perfected by any of the three Allies will immediately be demonstrated for the benefit of the blind soldiers of the other two, thus giving all the soldiers the greatest possible help in earning their living in the electrical industry.

3. The Clinical Value of Pupillary Changes.—Aaron Brav points out that important information can be obtained as to the local condition of the eye and also in regard to general constitutional disease by a careful study of pupillary phenomena. The following should be noted: (1) the form and color of the pupil; (2) the size of the pupil; (3) the contents of the pupil; (4) asymmetry of the pupils; (5) reaction of the pupil; (6) associated ocular conditions. (1) *Form and color of pupil.* Changes in the form of the pupil may be congenital or acquired. The former are seen in coloboma of the iris, when a portion of the iris is missing. An irregular pupil is always significant of some inflammatory process, engorged iris, or multiple tears in the iris. The iris becomes adherent to the lens capsule in various places and the form of the pupil takes a clover leaf shape. This is of special diagnostic value in differentiating iritis from acute glaucoma. A pear-shaped pupil, not congenital in origin, is always indicative of trauma. In arteriosclerosis, increase of the intraocular pressure, and in ophthalmic migraine, the pupil is more or less oval and eccentrically situated. In iridodialysis the pupil may have the shape of a half moon. In glioma of the retina, the pupil is yellowish red in color. A whitish gray pupil is the result of a cataractous lens. A slightly greenish pupil indicates a glaumatous condition. A golden reflex around the pupiliary periphery is diagnostic of subluxation of the lens anteriorly. A red pupil indicates hemorrhage in the anterior chamber. (2) *Size of pupil.* Ordinarily the size of the pupil is about 3 mm. in diameter; hyperopes have a small pupil, while in myopes it is larger. The size varies a little according to age and, of course, is influenced by the degree of illumination. Changes in size may or may not be accompanied by inflammatory symptoms. When not accompanied by inflammatory symptoms and not the result of the use of eserine or pilocarpine, miosis points to some spinal lesion or disease in the cerebrospinal system. Resection of the cervical sympathetic or traumatic destruction of the same ganglion will give a small contracted pupil. It is also seen in syphilis of the cerebrospinal system, in tabes dorsalis. Small pupils which do not react to light are diagnostic of syphilis. Spastic miosis is seen in meningitis, especially in children. A contracted pupil is also found in opium and tobacco poisoning. A dilated pupil points to a paralytic condition of part of

the third nerve and can be produced by irritation of the sympathetic; this is seen in postdiphtheritic paralysis of the accommodation. Mydriasis is also seen in syphilitic conditions of the eye involving the oculo motor nerve. Syphilis, diabetes, nephritis, and general paresis are all constitutional conditions which produce paralysis of the oculo motor nerve. Tumors of the brain also give rise to dilated pupils as a result of changes in the optic nerve. (3) *Contents of the pupil.* The pupillary opening may be filled with blood and appear red instead of black; this always denotes trauma. Dislocation of the lens, evidenced by a circular golden rim around the lens, may be traumatic in origin, may be caused by a blepharospasm during an operation, or may occur spontaneously as a result of sudden strain. Pus may also be present in the opening, as in keratitis or iritis, when the color of the pupil appears yellowish. Occasionally there are brownish deposits as a result of iritic exudation. Presence of the pupillary membrane in the opening may be congenital or acquired as the result of iritic inflammation; in such cases the pupil appears grayish white, and it is necessary to differentiate from pupillary reflex due to lenticular sclerosis. A tumor or cyst, or a syphilitic gumma, a tubercle or a metastitic abscess encapsulated may be seen. In some cases resort must be had to surgery, but many of the conditions yield to medicinal treatment and rest. (4) *Anisocoria.* Slight degrees of anisocoria may be seen in healthy persons, but a marked degree of pupillary inequality is always pathognomonic of some local or general constitutional disease. It may be seen where there is marked difference in the visual acuity of the eyes, in unilateral chronic iritis or glaucoma, or in unilateral diseases of the retina and choroid. Of the constitutional diseases, syphilis, tabes, progressive paralysis, multiple sclerosis, diseases of the kidney, liver, and nervous conditions may give rise to this phenomenon. It is more often acquired than congenital. (5) *Pupillary reaction.* Absolute immobility of the pupil when not caused by a cycloplegia or by local inflammation is probably due to some constitutional condition, such as syphilis of the nervous system, nephritis, diabetes, etc. The term absolute immobility is used when the pupil does not react to light, accommodation, or convergence; relative or reflex immobility means an abrogation of the light reflex, reaction to convergence being present. The former points to syphilis, while the latter is diagnostic of tabes and general paralysis. Hemianopic pupillary reflex, in which only part of the optic nerve fibers are involved, may also be found; this serves to differentiate between cortical lesions and lesions in the optic tract. (6) *Associated ocular conditions.* The author points out the necessity of studying the pupil from the various angles indicated and gives a number of examples to show the significance of the various phenomena considered in conjunction with other findings.

3. The Children's Year Campaign.—Grace L. Meigs. See MEDICAL RECORD, June 22, 1918, p. 1105.

8. Heat Stroke, with a Second Study of Cerebral Edema.—Pierce McKenzie and E. R. LeCount believe that the chief causative factor of heat stroke is the inability of the air about the body to receive more moisture since it is already saturated, together with the high temperature of the air. Other causes are tight and heavy clothing and a too small intake of water. The consumption of alcohol has been suggested as a factor, but further evidence of this is needed. There is no evidence that rays other than those of heat are productive of heat stroke. An infectious origin has also been suggested. In hot boiler rooms and similar places the attack may come on slowly, unconsciousness being preceded by dizziness, nausea, and weakness; there is profuse sweating, dryness of the mouth, a red or purple discoloration of the skin, shivering, and subnormal temperature or a temperature of 100° or 102° F., followed by death in coma. Heat stroke from insolation on the other hand may come on without warning. It is characterized by fibrillary twitching of muscles, vomiting, slow pulse, and temperature of from 105° to 117°. These forms may be classified as asphyxial and hyperpyrexial. The authors point out that the discussion which has arisen regarding the hyperemia of the brain and leptomeninges in such cases may have been due to the rapidity of the postmortem changes and the fact that observations were made at varying periods after death. One of the authors examined thirty-seven persons who died of heat stroke and the following alterations were found quite regularly: edema of the brain (in 22 cases) or leptomeninges (in 9 cases), or both (in 4 cases); marked generalized passive hyperemia, especially of the brain and lungs; edema of the lungs; hyperplasia of the spleen; cloudy swelling of the liver, kidneys, and myocardium, and petechial hemorrhages of the various mucous membranes and of the skin, with irregular and lessened yellow material of the suprarenal cortices. The edema of the brain tissue and splenic enlargement they consider of particular interest, adding that many standard text-books omit mention of any change in the spleen. The frequency of marked edema of the brain in these cases led the authors to attempt to estimate the amount of water present with more accuracy. At the time of the postmortem, pieces were therefore taken from the temporal lobes, and a separate estimate made for each. All the brains studied were from adults and control pieces were taken from brains of adults who had died by violence, and were examined in like manner. The average of water percentage for these controls was 79.7 per cent. Sixteen cases of heat stroke, which occurred in 1916, were all found to be of high water content and thirteen had a gross diagnosis of marked edema of the brain; the moisture percentages ranged from 81.16 to 83.78. In a series of six cases which occurred in 1917 the moisture content was rather less, the percentages being from 79.46 to 81.62. The authors state that the heat of 1917 was not so great as in 1916 and, as there were fewer cases in hospitals, patients may have received longer treatment which possibly lessened the moisture content of the brain. These results would seem to confirm the impression gained by finding, soon after death, the brain swollen with flat convolutions and tightly closed sulci, the arachnoid meshwork obliterated, and the parietal and visceral layers of the arachnoid in intimate contact. This condition is more marked on the vertex and sides of the cerebrum and is not invariably found with heat stroke. It is perhaps less constant than hyperplasia of the spleen, but deserves a place with the minute hemorrhages as one of the conspicuous alterations. McKenzie and LeCount also refer to the experiments of Woodyatt, who was able to produce high temperatures in dogs by dehydrating the animals by means of continuous injections of glucose; and to the observation by Maud Menton of an increased hydrogen-ion

concentration of the blood with low barometric pressure. As to prophylaxis and treatment of cases of heat stroke, these authors insist particularly upon the value of drinking water as a preventive, referring to Hunt's statement that three gallons of water are required by a man working on a hot day in the sun. With collapse and subnormal temperature, external heat and massage are advised. With hyperpyrexia, ice and ice-water are used in a variety of ways. Camphorated oil and other cardiac stimulants may be useful. Woolley advises solutions of sodium chloride and carbonate in water rectally and intravenously. Spinal puncture may give good results in cases where symptoms have continued for days with coma.

3. Epidemic Encephalitis.—S. A. Kinnier Wilson discusses the occurrence in England of a number of cases which might be classified as acute encephalitis or polioencephalitis but which do not conform to any rigid type. He points out that the subject is of particular importance at the present time in view of the public interest in food questions, since polioencephalitis is essentially the product of a toxic or toxi-infective agent. The author describes the cases under consideration as a nervous disease presenting features sufficiently indicative of encephalitis and characterized by pathological drowsiness amounting not infrequently to stupor. He remarks that this latter symptom has not hitherto been observed to anything like the same extent in poliomyelitis, endemic or epidemic, as it occurs in England. A number of cases are given in detail, and from a study of these Kinnier Wilson tentatively puts forward the following conclusions: Epidemic encephalitis is an acute nervous disease characterized by general and localizing symptoms; it attacks both sexes, irrespective of age; its onset is acute and, occasionally, it is fulminant in type. The general symptoms are: apathy, lethargy, drowsiness, pathological sleepiness, stupor, absence of initiative. Restlessness and restless delirium with reduction of mental activity to the degree of automatism is common; catatonia or flexibilitas cerea is frequent; delusions and hallucinations may occur, also incontinence, headache, giddiness, and vomiting. Epileptiform changes do not occur. It is to be noted, however, that even at the height of the illness the patient's response to questions is in act and word surprisingly accurate and rational. Temperature is usually normal. In a certain percentage of cases meningeal symptoms are present, but as a rule these are not well marked. Localizing symptoms: the commonest grouping is of the polioencephalitis superior type, *i. e.* a peri-aqueductal grouping. Paralysis to accommodation and corresponding indistinctness of vision or diplopia is a frequent early symptom, and the patient may even have the appearance, from mere drowsiness, of bilateral ptosis. Involvement of the lower cranial nerves is present to a variable extent and the predilection for motor as opposed to sensory cranial nerve nuclei points to specificity of action of the postulated virus of the disease. The limbs are more rarely involved, and the author points out that where this occurs the indications point to cortical, subcortical, mesencephalic, or pontine invasion of the corticospinal paths and not to cord invasion. Sensory symptoms are insignificant or absent and the diversity of localization precludes the likelihood of any constant or characteristic change in cutaneous or deep reflexes. No organism has been detected by any observer in the cerebrospinal fluid or in the tissues, with exception of a diplostreptococcus recovered by von Wiesner from the brain of a *Macacus rhesus* inoculated subdurally with an emulsion of the brain and cord from one of Economo's patients. It is significant, however, that a filtrate from the original brain cord of the same patient inoculated into a second monkey produced no symptoms. In cases where meningeal symptoms occur there may be definite pleocytosis. The duration of the disease is variable; it may end fatally in a few days or it may last for months. It is not certain whether there is a complete restitutio ad integrum in recovered cases. The pathological findings show meningeal congestion of cranial surface, and, microscopically, diffuse thickening of the leptomeninges, with scattered cellular exudates or with vascular congestion and perivascular cellular infiltrates, together with minor changes in the cerebral substance and cord. Similar epidemics have been reported by Economo in Vienna in the beginning of 1917, in Paris by Netter in the spring of this year, and in Queensland and New South Wales by Breinl. Economo coined the name *Encephalitis lethargica* and Netter adopted the term *Encephalite léthargique épidémique*, lethargy being in all cases a prominent feature of the clinical picture. Kinnier Wilson, however, prefers the term *Epidemic encephalitis* and concludes that what is new is the occurrence, in epidemic form, of cases of encephalitis not to all appearance due to the action of a known infective or toxi-infective agent, but presenting clinical symptoms any or all of which have been noted in various kinds of encephalitis with which the neurologist has long been conversant. He adds that unquestionably there is now afforded an excellent opportunity of solving the problem of the affection and thereby clearing up much that has been obscure in our knowledge of encephalitis in general.

3. The Abuse of Drainage Tubes.—Captain Frank Hathaway points out that war surgery has taught us that the two main principles of civil surgery are: (1) early and complete operation; (2) that secondary or mixed infection is worse than primary infection. Largely as a result of the work of Colonel H. M. W. Gray and his followers, war surgery has become a very different thing from what it was at the beginning of the war. Now wounds of the head, chest, abdomen (even with fecal contamination), and knee and other joints, are sewn up after early and complete operation, with excellent results. The first and most important effect of the war on the surgical world will be the abandonment of the drainage tube. Captain Hathaway says: "It is incredible that we have for years deliberately placed into the soft and pliable tissues of the human body a more or less rigid drainage tube with an opening passage for secondary infection to creep down." This fundamental fact was grasped by Sir George Lenthal Cheatle when he introduced his solid drainage tube with flanges; but he still kept to the rigid design. The method advocated by Captain Hathaway, and now used in military surgery, is that generally applied in tuberculous infections, namely, free incision, evacuation of contents, cleansing by mechanical means, or by the use of an antiseptic, and primary suture. Fomentations and weak antiseptic baths in the treatment of wounds simply encourage the staphylococci to come out of the pores of the skin and second-

arily infect the wound. Hathaway concludes, therefore, that in order to avoid mixed infections surgeons must practise primary suture far more than in the past, and give up completely the use of rigid open drainage tubes. Instead of draining where there is infection, Hathaway advises going to the opposite extreme, and not leaving a "passage" open unless it is absolutely necessary. If a passage is required to be kept open, for instance in an appendix abscess, he puts in a piece of soft folded rubber. If a secondary abscess or leakage from bowel should occur it will be dealt with by the inherent resistance of the body to infection, or should an abscess form it can be treated by a second operation, after adhesions have formed. To the above communication Sir Bertrand Dawson adds that with regard to empyemata, the pneumococcal cases do well with immediate closure after evacuation, but not the streptococcal; the latter need to be drained for two or three days, with or without Carrel tubes, and then they can be sewn up. Hathaway points out that streptococcal infections require different treatment, but that in civil practice streptococcal empyema is rarely encountered.

1. Observations on the Nature and Symptoms of Cardiac Infection in Childhood. III. Rheumatic Endocarditis.—F. J. Poynton refers to the importance of valvular disease in childhood as evidence of organic disease. Its lack of symptoms is easily realized when one considers the minute lesions of early endocarditis. Mitral endocarditis is extremely common in rheumatism and in fatal cases is practically invariable. It is important to distinguish between the classical mitral incompetence and stenosis. The latter is often regarded by the student as an advanced stage of the former, but this is true only in a restricted sense and the ordinary lesion of mitral incompetence will never give rise to a classical stenosis. Mitral stenosis is a subacute process involving the entire structure of the valve—a form of chronic inflammation more frequent in the female. Incompetence may be of little importance, whereas stenosis constitutes one of the most formidable of cardiac affections. In mitral incompetence in childhood, if the myocardium is severely damaged the case will run a disastrous course, compensation will never be effective, and invalidism quickly follows. If the myocardium is sound, with patience and care complete recoveries are frequent. If such cases are followed for some years, it will be noticed that the systolic murmur becomes indistinguishable from a so-called functional murmur in its behavior to change of position and cardiorespiratory phenomena; it is possible that in the course of cure the vegetations gradually shrink and the slight thickening left becomes of no importance. Cases which run an unsatisfactory course are remarkably resistant to treatment, a fact which may be due to weakness of the myocardium, adherent pericardium, and destruction of the tone of the valve ring. In mitral stenosis, it is of the utmost importance that early developments be carefully studied. Medical treatment is most unsatisfactory and the progress of the inflammation is so insidious that the condition may escape recognition until it is too late to do more than ease the suffering. The valvular change is the essential factor, the myocardium often being remarkably healthy. The association of mitral stenosis and chorea is of clinical interest. Poynton cites three cases in which he was able to trace the gradual development of mitral stenosis over periods of five to six years. He points out that the child may never complain of cardiac symptoms although the chorea is a reminder of the presence of active rheumatic infection. The history of the child's health is sometimes of value in diagnosis. The presystolic thrill is local and limited to the region of the heart beat; a systolic murmur is often audible but in some cases is never heard. A to and fro murmur, blowing in character, is not infrequently met with; this does not point to mitral stenosis but is a valuable sign in disastrous cases of incompetence. Since symptoms are usually absent in early cases of mitral stenosis, the development of definite symptoms in young children should be viewed with concern. Tachycardia may occur in childhood from the earliest appearance of the stenosis, but is not dependent upon the stenosis and may even predate it. In aortic and mitral disease, the feature of interest lies with the infective process, for such cases may terminate in a malignant or progressive endocarditis in early adult life. These combined lesions represent the majority of cases of aortic regurgitation in early life and the systolic mitral murmur should not be attributed to a relative incompetence of the valve secondary to the aortic disease; the mitral lesion is the earlier, and the result of endocarditis. Cases of combined lesions in which the aortic predominates are to all intents and purposes cases of aortic regurgitation, unless the mitral lesion has developed into a stenosis. In that event we have another important valvular defect in the combination of aortic regurgitation and mitral stenosis. Poynton lays particular emphasis upon nervousness as a symptom of aortic regurgitation in children. In such cases compensation is remarkably effective and the child may be wonderfully active. As a rule such patients do not die suddenly, but may succumb to a renewed attack of carditis. Later in life they may overstrain the heart, develop malignant endocarditis, or suffer from mitral lesion and its consequences. Malignant endocarditis in childhood resembles the condition in adult life, rheumatic infection being a frequent and common cause. Both simple and malignant endocarditis may occur in the cardiac valves in the same case and both forms may be produced by experimental inoculation with rheumatic infection. Poynton looks upon simple endocarditis as evidence of destruction of the micrococci by the tissue resistance, and malignant endocarditis as proof of the failure of that resistance. He does not accept the view that septic micrococci have a predilection for damaged and sclerotic valvular tissues, but thinks it highly probable that in the necrotic areas of vegetations micrococci may remain latent and spring into virulence. He asks, how is it that in written answers we find examinees insisting upon the multiple abscesses found in the viscera in malignant endocarditis? The great feature is the usual absence of such abscesses and the term arterial pyemia as a rule is quite incorrect. He adds that of course rheumatism is not the only cause of this condition, which may be produced by various infections, and concludes by the statement that the three cardinal processes in endocarditis are:—(1) the simple; (2) the sclerosing; and (3) the malignant.

The External Manifestations of Diabetes.—G. Rosenfeld recalls the fact often overlooked that the means of modern investigation frequently tend to place the older observations in the background, although these are excellent from the viewpoint of both diagnosis and prognosis. In the case of diabetes he refers to cutaneous desquamation resulting from a decrease of sebaceous excretion (this may be the cause of recurring furunculosis), the "purplish hectic" hue over the cheeks and upper border of the malar bone and the raw tongue which Rosenfeld regards as a bad sign. The often noted disproportion between the thin face and fat abdomen indicates disturbances of carbohydrate metabolism. It is to be distinguished from the obesity of alcoholics and that of true obesity.

Recovery from Changed Renal Functions in Chronic Kidney Affections.—F. Hirschfeld insists upon relieving the renal work in these cases as the basis of treatment. Diet, which should be aided by an air cure, should be poor in albumins and salt. This is in contradiction with

the modern tendency which only prescribes a restriction of those substances whose renal elimination has been shown to be insufficient. The writer has oliguria above all in view, which for the kidney represents a relative rest. The excretion of nitrogenous products and salt sets up an aqueous diuresis which is just what is to be avoided. The treatment finally ends in a re-establishment of the renal functions in the following order: function of dilution and later on the function of concentration. Hirschfeld has noted that after the cure, the ureo-secretory function may surpass a normal kidney in the rapidity of elimination. This property is slowly lost when more meat is added to the diet.

Münchener medizinische Wochenschrift.

The Treatment of Wounds by Deep Antisepsis with Bichloride of Isoethylhydrocuprein.—O. Asinn brings forth a confirmation of Klapp's views published in the *Münchener medizinische Wochenschrift,* May 7. The excision of all necrosed tissue and extensive infiltration of the healthy tissues with the quinine derivative have given him excellent results. He attributes this favorable effect to the fact that the bactericidal value of the product is of the highest order while at the same time it does not coagulate the tissue albumin, so that its dispersion is not limited in extent as is the case with other antiseptics. Asinn has also made an improvement in the preparation recommended by Klapp, by introducing gum arabic in the formula. The rapid absorption of the drug is by this means delayed and its effect in consequence is prolonged. The writer particularly advises to infiltrate the area of traumatism in successive layers and after reporting a few cases treated with advantage, he points to the fact that the drug seems to act well when primary excision of the wound is not done. This goes to show that Klapp's procedure is not successful merely from excision of the wound but that the injections of ethylhydrocuprein are largely responsible for the good results.

Paratyphoidal Diseases, Particularly of the Biliary Tract.—E. Fraenkel has studied a case of paratyphoid A, having a particularly septic evolution. At autopsy, he was able to obtain cultures of paratyphoid A from the blood taken from the heart. There were lesions of angiocholitis which had clinically shown themselves by icterus. Injected into guinea pigs, the "race" of bacillus grown from the patient's blood quickly set up a fatal syndrome quite similar to the paratyphoid in the patient, including the same bepatic changes. The relation between the bacteriemia, the angiocholitis and cholecystitis is supposed by Fraenkel to arise as follows: Development of the bacilli in the intestine, their passage into the blood, and elimination by way of the biliary tract. The cholecystitis which then develops can, in its turn, set up farther dissemination through the circulation. This vicious circle may, in some cases, necessitate surgical interference (cholecystectomy).

Deutsche medizinische Wochenschrift.

May 16, 1918.

The Weil-Felix Bacillus Immunity Reaction and Its Pathogenic Significance in Typhus Fever.—E. Friedberger absolutely maintains his former opinion, which regards the Proteus X 19 as the pathogenic agent of typhus. He enters upon a long and tiresome controversy against Otto, who is of opinion that the agglutination of the Proteus X 19 is only a phenomenon of para-agglutination. The article does not offer anything new.

Milk Therapeutics.—R. Müller endeavors to legitimatize his treatment of infectious processes by the injection of sterile milk. Opposed by a number of surgeons, Müller maintains that this treatment has given excellent results in typhoid fever, gonorrheal complications, acute articular rheumatism, erysipelas, ocular and otic infections, etc. The theoretical reasons which led to a trial of this procedure are those drawn from the non-specificity of vaccines and sera in general, which appear to act as much by the general reaction which they provoke as by their directly antibacterial effect, for example: The effect of the deuteroalbuminoses in tuberculosis, pyocyanic vaccine in typhoid, etc. The increased action of intravenous injections as compared with intramuscular injections has led Müller to attribute the therapeutic action of the albumins to "a shock which gives full play to the inflammatory factors." The choice of milk rather than some other albumin is merely because of the facility of obtaining it. Finally, the writer records the happy evolution of sixty cases of epididymitis treated with milk injections. He particularly advises the procedure in cases of bubo to those who desire to get an idea as to what may be attained by this treatment.

Serious Anaphylactic Shock Following the Injection of Milk.—R. Lubliner reports a serious case of shock from milk injections which rather throws cold water on the opinion maintained by Müller in the above article.

Wiener medizinische Wochenschrift.

June 1, 1918.

Galician Dysentery.—F. C. Krasa finishes his examination of this question with the conception of a special ameba as the causal factor of the epidemic in question. Certain amebas are common in the intestinal tract and are not pathogenic, and on the other hand certain circumstances may reduce to a very low proportion the number of cases which can be verified bacteriologically. One should also be reserved in describing new agents of dysentery. As to treatment, Krasa prefers a polyvalent antidysenteric serum.

Surgery of War.—R. Bárány confines his article to a study of the evolution of surgical methods of warfare in the various belligerent countries. He particularly insists on the increasing adoption of primary excision of wounds and their immediate suture. This method gives excellent results even in brain and joint injuries.

Révue médicale de la Suisse romande.

March, 1918.

Relations Between Mitral Stenosis and Pulmonary Tuberculosis.—Burnand calls attention to three alleged relationships which appear to be more or less antagonistic among themselves. One is that the valvular lesion opposes the development of tuberculosis through setting up chronic pulmonary stasis. Another states that the cardiac lesion may itself be of tuberculous nature and that several types even of the latter exist. The third view is that when a clinical tuberculosis follows a mitral lesion it is not a true bacillosis but a pseudotuberculous syndrome. These three conceptions of relationship need not exclude one another and it may even be possible to coordinate them. There is no doubt that endocarditis involving the mitral orifice is sometimes a local tuberculosis of a benign type. In such a case it could be associated with other manifestations of tubercle, especially in the apices of the lungs, whether active or latent. A number of well known clinicians and pathologists have attested the relatively benign character of this association. The so-called pseudotuberculosis of mitral lesion is, in the author's opinion, also an example of benign tuberculosis without bacillary finds. Thus it is possible to bring all three associations under a single head. The author now relates a case in a young man, a poor physical specimen since his birth, who presented congestion of the right apex interpreted as incipient tuberculosis. There was neither fever nor cough. Examination of the heart showed classical mitral stenosis. There was also a history of syphilis, the seroreaction being positive. Mitral stenosis is of course very rare in the male and the author believes it to have been due to tubercle in this particular instance. The cardiac localization preceded the pulmonary lesion and doubtless went back to the patient's childhood, for at the age of 12 he had what would ordinarily be regarded as acute articular rheumatism but what the author prefers to regard as an example of Bucet's acute tuberculous pseudo-rheumatism. About 10 years elapsed before the appearance of the pulmonary lesion, which was at its outset of a febrile type but gradually became non-febrile.

(*Concluded from page* 218.)

SECTION ON OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY.

Second Day—Friday, June 14.

DR. HENRY T. BYFORD OF CHICAGO IN THE CHAIR.

Avoidable Traumatic Abdomen.—Dr. JOHN B. DEAVER of Philadelphia presented this subject. The finding at operation of a pair of eight inch hemostatic forceps, which had been left in the abdominal cavity at an operation done twelve years previously by an unknown operator, led the speaker to discuss the unnecessary trauma which such an oversight might cause, and also to consider other avoidable abdominal injury, such as perforation and rupture of the uterus, which, with proper instruction, technique, and judgment could also be avoided in the vast majority of instances. In the case cited, the patient was a woman 49 years of age, the instrument had separated and found lodgment in different portions of the body. A spontaneous ileosigmoidostomy had occurred. After removal of the foreign body the patient made an uneventful recovery. Proper organization of the operating room would have prevented this mishap. Absolute quiet was essential, with well trained assistants each assigned to a particular task. Each instrument and piece of gauze should be accounted for. Some surgeons were apt to plead extenuating circumstances for having left foreign bodies in the abdomen, but this occurrence occasioned great suffering and a probable lawsuit. Nature tended to protect itself from the foreign body, and it might pass off through the rectum, but often a secondary operation was necessary. Another avoidable traumatism was perforation of the uterus which was apt to occur during curettage, if care was not exercised. The expert would recognize at once unusual tissue. Careful examination of the condition of the uterus by nature's best weapon (the finger of the expert surgeon) was the best safeguard. Perforations had been known to be caused by caustic solutions. Occasionally rupture of the uterus had occurred through the use of pituitrin. The only treatment was abdominal section at the first sign of rupture. Conservation had become the watchword of the present crisis, as it had always been in medicine. Nothing should be left undone now when this warning note against the wastage and demands of warfare made it more than ever imperative to bend all efforts toward conserving life, preventing suffering and the unnecessary drain on the service of the sadly depleted staffs of the civilian hospitals.

Dr. S. E. TRACY of Philadelphia said he had an experience with one patient who complained of pain in the left side of the abdomen. Upon examination he came to the conclusion that she had a malignancy. The abdomen was opened, the transverse colon was taken out and an anastomosis done. Examination of the specimen revealed a long piece of gauze with part of a gauze sponge. Seventeen years before this woman had had a hysterectomy done and she had shown no symptoms at all until she came under observation.

Dr. B. SALATICH of New Orleans said a surgeon was telling him of a wonderful operation he had done. He resected 3 feet of the bowel and the patient got well. In curetting a patient he did not see until the bowel was coming out of the vagina that he had made a perforation. He resected 3 feet of intestine and then boasted of the wonderful operation.

Dr. EMIL NOVAK of Baltimore said that Dr. Deaver was kinder to the gynecologists than he usually was. In connection with perforation of the uterus a striking case might be mentioned of a colored woman. The woman thought she was pregnant and introduced a large splinter of wood into the vagina. After a while she felt a desire to defecate. She noticed something hanging down from the vagina and cut it off with scissors. This was a loop of the intestine. She was brought to the hospital in a moribund condition and died of peritonitis. Dr. Deaver had done a service to gynecology in his warning about curetting. This was usually a simple operation and with proper precautions perforation ought not to occur. It usually occurred on the long stroke of the curet. The curet should be allowed to slide in gently and the sharp stroke could be made coming out. One case of rupture of the uterus could be mentioned which was not attended with the usual tragic conditions. A cesarean section was done 6 weeks after expected labor and a large macerated fetus was removed. It was well down in the pelvis. There was only moderate pain and no symptoms of collapse.

Dr. A. WALKER of Anthony, Kan., said that he knew a case where an inexperienced physician removed 40 inches of bowel through a perforation in the anterior wall. The uterus was retroflected.

Dr. A. B. BUTT of Davis, West Va., said that some day this accident would occur to Dr. Deaver, as it had occurred to many of them. Interest should be directed toward the prevention of accidents. At Dr. Murphy's clinic sponges were counted and instruments looked for. The impression should not be allowed to get about that accidents were entirely avoidable. This was not always so.

Dr. DEAVER in conclusion said that his case was unique. The adjoining bowel was perforated and yet the patient had survived for a number of years without symptoms.

How Surgeons Can Help Win the War.—Dr. FRANKLIN H. MARTIN of Chicago made this address, which was not given in the form of a paper, but as an informal talk. It was thought that the place of the obstetrician was to remain home and take care of the women. Those who were abdominal surgeons and who were eligible for the Reserve Corps should immediately enroll in the Reserve Corps. There was no man or woman who was more needed in the service at present than the abdominal surgeon. The point to be impressed upon the members of the Section was the real, serious need of their enrolling in the service. No class of officers was needed more than doctors. One doctor was equal to a great many fighting men; estimated by the official tables of the enemy, every doctor was equal to 500 to 1000 fighting men. If every man eligible for the Medical Reserve Corps were to go, still there would be 50 per cent of the men left to carry on the work, and all of the women. The medical schools might not be run as efficiently as they had been, but still they could go on, and some of their teachers were needed far more at the front. They never were needed more than now, and the need would go on becoming greater. Dr. Martin said that if any man came to him after the meeting and said, "Doctor, I want to help my country," he would be told it was the simplest thing in the world. He had merely to fill in the papers for the Surgeon General saying when it would be convenient to come. The man might then say, "Well, doctor, that is all right, but——" Then reasons would be given—the man had an expensive family; he had a private hospital on his hands; he could do better if he stayed at home to teach. He would not. The man who made that statement was a conceited ass. He was not needed so much here as over there, no matter who he was. If the man was not eligible for the Reserve Corps, there was another course open. A letter should be written to the Council on National Defense, Medical Department, asking for papers to the Volunteer Reserve Corps, which was open to all men and women not eligible to active service. After having made the application and being made eligible for the Volunteer Corps, the insignia would be sent, and the man would be accepted as a Volunteer. There was a place in the Government for everyone. The Government must make the choice, not the man himself, and he should be willing to accept the decision of the Government unless he wished to be classed with the pacifists and the disloyal. A man should enroll in the Medical Reserve Corps or with the Volunteer Reserve Corps.

Dr. ALFRED A. STRAUSS of Chicago said he knew a number of cases, and he was in this class himself, where a young man, because of the fact that he happened to

be born in Germany, was considered ineligible. He had been brought over to this country as a very young child. All his interests and associations were with America, and there was no more loyal citizen, yet he was prevented from giving his services in this crisis. Some men he knew, similarly placed, were giving their services as cooks and orderlies, rather than be left out. He felt that if the need were so great for abdominal surgeons, there should be some arrangement by which the services of men like himself could be accepted. He felt sure that if Dr. Martin would take the matter up the law could be amended in this particular.

Dr. Martin said that this same difficulty had occurred in the drafting of medical students. They were asked to remain at their college and finish their courses. Also some young men were asked to stay at home and teach, in pathology and other branches, where their services were needed. The provision was made that when these men were drafted they should be placed in the draft Medical Reserve, with the understanding that they were to graduate into the Officers' Medical Reserve Corps. If this law had not been already carried out, it was under immediate consideration, and it would work out so that men who were eligible for work in the Medical Reserve Corps would not be obliged to waste their time in other kinds of work. The Surgeon General had been so fair in his settlement of all kinds of questions that no doubt this matter could be adjusted with entire justice to every kind of claim.

The Question of Operation in Gunshot Abdominal Wounds.—Dr. Joseph Rilus Eastman of Indianapolis read this paper. He said that notwithstanding the experiences of the present war had modified the old views as to the advisability of abstention in abdominal wounds, there still remained, notably in France, a rather sharp division between what were designated the abstentionists on the one hand and the interventionists on the other, the former group basing a diagnosis of penetration and perforation, as well as treatment, on the evolution of symptoms; the latter group making the complete diagnosis by laparotomy, and applying immediately or within the first few hours, the appropriate surgical treatment. Unfortunately, the most experienced surgeons would occasionally find more or less difficulty in diagnosticating penetration and perforation before operation. There was not always present an aperture of exit, in which case it was difficult to determine the course of the missile, for all missiles might ricochet. There were a few recognized rules to follow; for example, the closer together the wounds of entrance and exit, the less the chance of penetration and Rochard had declared that if a wounded man did not cease to complain of abdominal pain, a perforation was almost certain. Rochard also said that if a patient passed gas at the anus, there was no perforation. All rules failed sometimes, with the exception of these three which proved the existence of perforation: escape of bowel contents from the wound of entrance or exit, protrusion of perforated gut at the wound, and passing of the missile by the anus. At the beginning of the war nearly all surgeons were abstentionists, but now the general opinion inclined the other way. In support of intervention, the Interallied Surgical Congress of last March expressed the view which was the most authoritative available, that all intestinal wounds should be treated by laparotomy, with suture.

Dr. D. Eisendrath of Chicago said that the experience of surgeons in a large city was quite comparable to that seen at the front. In penetrating gunshot wounds of the abdomen the treatment was the same in civil life. In combined abdominal and thoracic injury the injury to the abdomen was often overlooked. Often after a gunshot wound of the chest there was abdominal perforation. Laceration of the chest wall and of the liver often occurred together. Formerly these cases were treated by non-interference, but since the Somme, surgeons, led by Duval, made an early exploration of the diaphragm for injury to subdiaphragmatic tissues. In civil life, as in war surgery, there were two or three infallible signs of perforation and if these were present the surgeon should not take any chance. It was better to do an unnecessary laparotomy one hundred times than to overlook a single case of perforation. Rigidity of the abdominal muscles was one of the important signs of beginning peritonitis. Tenderness was often also present, and the third sign was the increase of pulse rate. Increased leucocytosis could not be depended upon. Suprapubic drainage was a useful measure, but it was no use unless the perforation were repaired. In perforation of the upper abdomen there occurred a hypertoxicity from the activity of the pancreatic secretion. The picture was one of acute pancreatitis, with collapse, pulselessness, cyanosis, and distinct evidences of peritonitis. A laparotomy should be done and, beginning at the ileocecal valve, the gut should be followed up the coil of the small intestine, and then replaced; later, if no perforation was found, a similar procedure should be followed with the large intestine. This was a rough and ready way, but very practical.

Dr. J. Y. Brown of St. Louis said that he was an advocate of early operation. He agreed with Dr. Eisendrath that the principles of this surgery were the same as in civil life. A small penetrating wound of the abdomen would give no symptoms, without injury of the viscera. Another type of wound that appeared similar, but was very deadly, was one in which the intestine was injured in a bloodless portion of the bowel. That gave no symptoms, in contrast to wounds of the mesentery where there was immediate hemorrhage. Every case should be explored, as, while waiting for symptoms, peritonitis might develop. In regard to combined wounds, penetrating the chest and diaphragm, with pneumothorax, a rib could be resected and if perforation was found, a laparotomy should be done. In regard to wounds of the abdomen, the transverse column must be packed, the small bowel followed down to the ileocecal valve, and then beginning again the intestine should be followed up. In wounds of the stomach the omentum could be laid back, and the stomach turned back and the lesser peritoneal cavity may be looked into. It was the overlooked wound that killed the patient. The arguments put forth by civil and military surgeons that patients could recover from perforation without operation were worthless. Those who recovered had no perforation of the viscera.

Treatment of Incisional Ventral Hernia by the Transplantation of Fascia Lata.—Dr. Willard Bartlett of St. Louis presented this communication. A few essential points were noted. The lesion with the ring and sac was due to stretching of the abdominal wall in consequence of nerve section at previous laparotomies. Ninety-one cases were analyzed, in twenty-four of which the previous operation had been done by the reader of the paper. There was known cure in 61 cases and failures in 6, 2 due to implant of wire filigree, and 4 to overlapping, the latter procedure being of use only where the tissue was not too thin to hold in place. In order to effect cure the damage to the wall as well as the increase of pressure must be treated. Weight must be reduced and attention must be paid to cardiac and respiratory conditions. Constipation and urinary retention must be removed. Vomiting and meteorism must be prevented. Increase of blood pressure must be noted, as often tight closure of the abdomen caused a rise in blood pressure. No one operation was indicated in all cases, but in most a transplantation of the fascial flap would be a help, either by itself, or superimposed on some other method. Methods of treatment were by reconstruction of the wall, by flap inversion, by filigree wire work in emergency, finally by free fascia transplantation.

Dr. Van Hook of Chicago said it was difficult to close a hernia where the intraabdominal conditions had been modified. Laparoplasty was a method that was useful; by this method the anterior plate of the rectus sheath was dissected off and combined with the external oblique muscle. The large flaps corresponded to the lower quadrants of the man's breast, and these could be brought down to a lower point and the median line thus powerfully reinforced. The flaps could be crossed and united lower down on the abdomen. To diminish the capacity of the abdomen the patient was put in the Trendelenburg position with the thighs flexed on the abdomen and the legs upon the thighs. This would flex the spine and relax the anterior abdominal wall.

Dr. A. A. Strauss of Chicago said that he had gotten similar results in experimental work in dogs, that is he took the anterior sheath of the rectus away and never got hernia even with a great defect. It was not

so much the defect of the fascia, as of the strain following abdominal operation. He had had 3 cases with fascia lata transplants. In two there was infection, but the tissue took. If the transplant did not take it was the fault of the type of suture used. Catgut was not of such nature as to allow granulation to occur. If the right ligatures were used, the fascial transplant would survive infection.

Dr. McGEE of Burlington, Iowa, said that one point was not clear. Dr. Bartlett attributed hernia to increased intra-abdominal tension, yet one speaker said he shortened the anterior wall of the stomach to cure the hernia. These two statements seemed at variance.

Dr. HERTZLER of Kansas City said that too much had been said of the mechanical factors, and too little of the physiology of wound healing. If the primary elements of wound healing were interfered with, hernia would result. In non-infected cases if the physiology of healing had been conformed with, no hernia would take place. Exudative material, as from cysts, would prevent healing.

Dr. B. SALATICH of New Orleans said that a good many failures were due to the fact that the fascia was not cleaned of all fatty material. In Murphy's reconstructed joint cases, he left fat on the fascia to have two sliding surfaces, one on the other, until the catgut was absorbed. In all fat cases, in repairing ventral hernia a drain of a few strands of silk-worm gut would be found of value. It would be surprising how much exudate would ooze out. This would otherwise have been retained and cause suppuration.

Dr. GOLDSPOHN of Chicago said that they should keep in mind the etiological factors in these hernia cases. Some exceptional cases were practically incurable. The overlapping operation was very serviceable, but it had its limitations. There came a time, after many operations, when the material was insufficient. In one case, an obese woman, who had originally had a gynecological operation, and subsequently 3 hernia operations (one operation was done with fine silver chain instead of filigree) there was a recurrence every time. Finally transplantation of strips of fascia lata was done, these strips were 15 inches long and 3 inches wide and were placed transversely over the abdomen. There was a serous discharge for 2 months, but it finally stopped, and the patient was now in better shape than she had ever been.

Dr. S. C. WILLIAMS of Chippewa Falls, Wis., asked what type of sutures were used in the transplant.

Dr. W. P. MANTON of Detroit said in the early days of surgery a through and through suture was employed. Sir Spencer Wells was extremely careless in uniting the abdominal wall and had a number of post-operative hernias.

Dr. W. BARTLETT in conclusion said that he appreciated the interesting suggestion of Dr. Van Hook. He had not tried this method. Dr. McGee had spoken of increased tension, this might occasionally cause symptoms of obstruction. In one case this had happened, when, after a week of extreme discomfort, tight sutures had given way, and with a sigh of relief the patient started to recover. As a rule, however, abdominal tension was low. Dr. Goldspohn had confirmed what he had said about the fascial flaps holding even after infection. He had put the soft pedal on this fact, thinking that perhaps the cases cited were exceptional. They seemed to be borne out, however, by other experience. He had employed catgut prepared in tannic acid. This could be treated so as to last 6 months in muscle tissue. It could not be absolutely standardized, but it had good lasting powers. The tissues of different individuals reacted to suture material in different ways so that no hard and fast rule could be made. Why some wounds tended to develop hernia by weakening of the wall and why others did not had to do with the physiological location of the wounds and methods of closure. Incisional hernia was more common when through and through suture was used than with layer suture.

Infantilism and Other Hypoplastic Conditions of the Uterus.—Dr. EMIL NOVAK of Baltimore presented this communication. Infantilism of the female genital organs was frequently observed in women, who presented no other recognizable defects in development. The importance clinically of this condition was (1) its association with menstrual disturbance; and (2) that it constituted the anatomical basis for sterility. The study of the embryological status of the uterus was necessary for the proper understanding of the subject. Twenty-six uteri were studied, varying in age from the twelfth week of fetal life to the fourteenth year of postnatal life. During fetal life the cervix preponderated over the corpus uteri; at the very end of fetal life a striking acceleration of the growth of the fundus and cervix was noted, after birth there was shrinkage and involution of the fetal uterus, and during childhood the disproportion between the cervix and the corpus was lessened. Anteflexion and also retroflexion were often marked at this stage. Puberty brought about a marked stimulation of uterine growth by means of ovarian secretion. The corpus uteri was especially affected. The anatomical division of the uterus into two segments, corpus and cervix, was usually accepted, but Aschoff in 1906 found that the uterus was really composed of three segments: the corpus, the cervix, and the isthmus uteri. The isthmus was found to present certain histological features which had distinct significance in the explanation of physiological and pathological occurrences. The lower uterine segment of the parturient uterus was derived from this portion. Gynecologically this segment was of importance, inasmuch as flexions of the uterus always took place at the isthmus, both congenital and those of later life. The gynecologist would do well to study uterine function from this point of view, that is that the three segments of the uterus had separate function and were under different endocrine influence. This viewpoint was more conducive to fruitful observation and study than the habit of looking upon the organ as functioning *en masse*. In regard to types of hypoplasia,—these might occur either as arrest of growth, or as arrest of differentiation. The two principal types were: (1) *uterus fetalis*, in which development was arrested in the embryonic stage; (2) *uterus infantilis*, where the arrest occurred during the period of infancy and childhood. In the latter form the cervix still predominated over the corpus but the two were clearly differentiated. The fundus was better developed, but the broad convexity of maturity was lacking. Anteflexion was often found in this type. There was also a third type: *uterus subpubescens* in which arrest of growth occurred at the prepubertal period. All grades of this hypoplasia might be present. Anteflexions were very common. In regard to function, both menstruation and reproduction were profoundly influenced by uterine hypoplasia. In one type, the "amenorrheic," menstruation was very scanty. In the second group the chief symptom was dysmenorrhea, although sometimes the flow was normal or even excessive. Symptoms were divided, as regards the two groups, into two kinds: disturbance (1) of menstrual function (2) of reproductive capacity (sterility). In regard to treatment, this was still unsatisfactory, as the underlying cause of the condition was still unknown. Which of the ductless glands were concerned was as yet an unsolved problem. Aside from the probabilities of endocrine therapy, the matter was a very composite one. Amenorrhea, dysmenorrhea, and sterility were all stages of the disorder. Unfortunately the tendency was to treat the symptoms and not the disease. The two drugs most useful in dysmenorrhea were, unfortunately, morphine and alcohol, both to be avoided on account of habit formation. Atropine was without this disqualification and was of decided value. Curettage was of no value in this condition, as it tended to remove perfectly normal endometrium. The use of the stem pessary, by Carstens, was better than simple dilation, but occasionally it was the cause of a troublesome endocervitis. Caution in its use was therefore necessary. The plastic operations on the cervix, based on the impression that cervical stenosis existed, were without excuse and should be abandoned.

Paravertebral Anesthesia, with Report of One Hundred Cases.—Drs. N. R. MASON and F. C. W. KONRAD of Boston presented this paper, read by Dr. KONRAD. This form of anesthesia, combined with scopalamine-narcophin seminarcosis was the ideal form of anesthesia when reduction of surgical shock was of paramount importance, in those cases classed as poor surgical risks, or those so handicapped as to be practically inoperable. Twenty-six of these cases were analyzed. They in-

cluded carcinoma of the cervix during pregnancy; malnutrition, arteriosclerosis and senility in an extreme postoperative ventral hernia; toxemia of pregnancy with termination of the pregnancy after the pulse had risen above 140 per minute; failing cardiac compensation in pregnancy; blood pressure of 240 mm. with fibroids of the uterus; diabetes; ether idiosyncrasy; delirium tremens; and active pulmonary tuberculosis. In no case was there any untoward symptom after anesthesia except in the case of alcoholism. One case with ulcerating procedentia died 7 days after operation, of pneumonia. The reduction of shock was most marked and the only sensation noted was the first prick of the needle. Additional ether was given in one or two cases during the operation, but later studies tended to show that this was an unnecessary procedure. In some cases the packing back of the intestines seemed to occasion discomfort. A certain class of patients registered any sensation as pain by crying out or struggling, but there was no after memory of sensation. In order to do the nerve trunk anesthesia the patient was placed in a sitting posture with the back arched. The skin was prepared with iodine and alcohol. The 6th dorsal and the 3rd lumbar were located. In anesthesia of the neck the column was entered from the side. In the coccyx the 2nd sacral foramen was entered.

The needle used was 9/10 cm. in diameter and 5 cm. capacity. Patients under this anesthesia were always semi-conscious, and it should be remembered that bright light, loud noise, or any disturbance made the patient restless. A preliminary dose of veronal was given the night before and the injection of scopolamine-narcophin 2½ hours before operation. Scopolamine tended to cause lip dryness and this could be counteracted by moistening the lips with water or with salve. The method has been successfully carried out in 69 cases where the condition of the patient made ordinary narcosis precarious. There was no contraindication, unless immediate anesthesia was required.

Dr. A. E. Hertzler of Kansas City said that like standing on one's head, paravertebral anesthesia could be done, but it was time-consuming. It took at least a dozen injections. Unless a large amount of fluid was used, the results were uncertain. He preferred spinal anesthesia with novocain. The sacral paravertebral anesthesia looked uncalled for, one could get into the sacral canal with less trouble and more certain result.

Dr. F. C. Konrad said that the difficulties disappeared with practice. It was not for the surgeon to do, but for the anesthetist. The loss of time therefore to the surgeon was negligible. The patient did not need attention after operation, therefore one could have a continuous flow of patients. The amount of fluid was large, but the location of the injection precluded danger. Absorption was slow and anesthesia was prolonged. Elimination went on at the same time as absorption. Spinal anesthesia had accessory effects which could not be entirely eliminated. There had never been any untoward effects with this method, therefore even first attempts were without danger. The needles used were small and less likely to be broken.

The Pathology of Hemorrhagic Myomas and Their Relation to Sarcoma.—Dr. A. E. Hertzler of Kansas City made this presentation. The clinical significance of certain types of myomatous degeneration was studied. The development of hyaline dengeration of the vessel walls was illustrated and it was shown that hemorrhage into the tumor substance was due to changes in the vessel walls. The time of hemorrhage in some myomas could be determined by the clinical history of the case. This was due to increased vascularization during development. An interesting point was the chemical change in the blood, a lytic power being developed and a lack of calcium being found in the exudates, although just what significance this had was not as yet known. The whole question of sarcomatous development from hemorrhagic myomas was probably strictly a chemical proposition.

Dr. Emil Novak of Baltimore said that Dr. Hertzler's work was interesting. He, however, did not feel convinced that these cells derived from the blood vessels were becoming sarcomatous cells. One should be conservative about these statements. Most myomas showed hemorrhage and hyaline degeneration. A regular foreign body reaction was stimulated and the formation of giant cells took place. In a large ovarian cyst what seemed to be giant cell sarcoma was merely a reaction to an old hemorrhage by cells scattered in the granulation tissue. It was very easy to misconstrue a picture of this type. If Dr. Hertzler could show the actual transition of the cell he would put his demonstration on a firmer basis. This could be demonstrated with muscle cells, but hemorrhage did not tend to have this development in other parts of the body. The whole subject of sarcomatous development was of great importance and every myoma should be cut open before it left the operating room. Naked eye examination often would show the typical areas of raw-pork appearance. If these were shown a complete operation should be done. One reason often for unfavorable prognosis in these cases was that a sub-total hysterectomy was often performed, and later the total hysterectomy became necessary. This was as bad as operating on a carcinoma in two stages. There was little in the clinical history to show the point of sarcomatous degeneration. The overlooking of such cases, therefore, occurred rather frequently. At Johns Hopkins 1400 cases of myomas were collected and of these 17 were sarcomas. Thus it was seen that at least one per cent of these tumors might be potentialities for evil and they should be cut open and examined.

Dr. Van Hoosen of Chicago said that she could not take away anything from Dr. Hertzler's paper, but that she could add interesting facts concerning the reverse of the malignant process. These tumors might be converted into fibromas. A few slides were shown illustrating this process. In a case of inoperable carcinoma of the floor of the vagina, 9½ grains of emetine hydrochloride was given in 200 c.c. of physiological salt solution intravenously. In a week's time the hemorrhage and discharge had ceased. There happened to be no emetine in the hospital and a repetition of the dose was delayed. Finally, the patient was so anxious to repeat the treatment that she sent an interne out to get the drug and the dose was repeated. The first time there had been no reaction. The second injection produced a tremendous reaction and the patient died in one minute. It was not known at the time that the patient was at the height of sensitization after the first dose. At the post mortem the uterus was removed. There were no metastases and the growth was found greatly shrunken and the carcinomatous tissue was found to be replaced by fibrous tissue. In another case where small doses were given and gradually increased, the patient developed a toxemia, but there was nothing left of the mass. Very wonderful results had been obtained, but as yet the proper dosage of the drug had not been determined. A patient was shown, exhibiting complete arrest of the carcinomatous process.

Dr. A. E. Hertzler said that in the myomas that he showed there was hemorrhage in only a small fraction of the cases. In fully 90 per cent there was no blood in the balance of the tissue. He had found 4 per cent of sarcomas, the figure being therefore much higher than Dr. Novak's. One should be familiar with development of bundles of fibrous tissue *in vitro*. These things were brought together not so much to indicate a fact as a possibility.

The Radical Treatment of Cancer of the Cervix by Igni-Extirpation.—Dr. E. A. Weiss of Pittsburgh made this presentation. Radium and *x*-ray treatment were palliative measures only. The operative technique should be improved. The Wertheim operation was admirable, but there was a high primary mortality, and the questions of infection, hemorrhage, shock, and recurrences had to be considered. These all had a high incidence in operations on cancer of the cervix. Most operators agreed that heat produced the best operative results; 45 per cent of patients survived the 5 year period after this technique. In Wertheims' operation 25 per cent. survived the 5 year period. In the Werder operation the cautery was found better than the knife in that it effectively prevented recurrence by implantation of cancer cells in the vaginal areas. Large blood vessels were easily controlled by the cautery. Down's electric endotribe was used. The absence of bleeding tended to eliminate shock. A Percy flat blade, heated to a dull red heat, was most satisfactory. A high amputation of the cervix could be effected without bleeding, the cancer mass being manipulated as little as possible.

In searching for metastases it should be remembered that thickening of the tissues might be merely inflammatory. In doing the operation injury to the bladder and ureters was avoided by drawing the ureters aside and retracting the bladder. The knife was applied to the parametrium, the ligaments being made tense. Advantages of this method were the lowered mortality, less pain and shock, smooth convalescence, and higher percentage of permanent cures.

Dr. A. GOLDSPOHN of Chicago said that this operation was a valuable achievement but it should be permissible only for the expert gynecologists, not the rank and file of the profession. In the days of Lawson, Tait and Price, students were apt to listen to their teachings and then go home and try to do the same. The result was they populated the graveyards. There was a difference between knowing how and actual performance. The high mortality of these cases from 18 to 29 per cent was stunning to a patient who went to the doctor not because she was sick, for she was up and doing her household duties, but because she had a suspicious bloody discharge, and to hear that she had only two out of three chances to live was startling. It was therefore difficult to educate the public to come for early operation. There was a difference between the Wertheim and the Werder operations of 11 per cent. This was due to protection of the ureter. The uterine artery lay just in front of this structure and when the anterior cul-de-sac was opened the bladder and ureter could be separated and set to one side. A fairly radical operation could then be done. If metastases had extended into the parametrium then the ureter was dissected. It was, however, unnecessary to do desperate operations on people who had already one foot in the grave. It was of far more importance to educate the public to put themselves at an early stage in the hands of a competent man. The use of the cautery was equivalent to that of radium or the *x*-ray. Down's clamp had been lying by for years but recently its utility had been recognized.

Dr. GEORGE GELLHORN of St. Louis said that igni-extirpation of the uterus by means of the cautery had at one time (1894-8) promised excellent results, but after careful study of the records the operation, while a good one, was not considered so satisfactory as formerly. Its advantages were that recovery was easy and there was no implantation of metastases near the operative site. There the advantages ended. Its limitation was pronounced. It was applicable only in early stages of the disease. Most cases were too advanced for its application. It was not easy to pull the uterus into the vaginal opening. Dr. Weiss had said he pulled the cervix down but it was impossible to pull down a cancerous cervix.

Dr. L. SCHMIDT of Chicago said that the success in operation depended upon entire eradication. There would be no recurrence if all the cancer cells were removed. An exploratory laparotomy must be made and if there were any invasion of the surrounding tissues a total extirpation should be done. Such a condition was rarely found. In inoperable cases radium and the *x*-ray could be used to modify the conditions, and later the Werder technique could be used to liberate the cervix through the vagina. The abdomen was then opened and heavy radiation used with good results.

Dr. VAN HOOSEN of Chicago said that if the patients could be subjected to the 9 grain dose of emetine hydrochloride intravenously a fibrosis could be brought about in one week. The stiffness and infiltration of the surrounding tissues would disappear and the case would become much more easily operable.

Dr. J. L. KEEFE of Providence, R. I., said he had used the electric angiotribe in 200 cases. In 90 cases of thyroid operation he had found it valuable. It prevented hemorrhage and it was not hard to learn how to use it. If it was dipped in oil the tissues would not adhere to the blade. One should experiment on a piece of steak. The statistics of Werder and Weiss were better than any obtained hitherto. The heat of the cautery certainly did destroy the cancer cells.

Dr. CURTIS of Portland, Ore., said the pendulum was gradually swinging in favor of heat. Experience was as yet lacking in the use of this method, but it appeared to be excellent in well marked cases.

Dr. WEISS said that he had expected to receive sharp criticism. He was not condemning the Wertheim operation, but he had had a distressing experience with this method, and the plan he had advocated was rather a rehash of old methods than a new one. In the early operation illustrated in the slide, if the vagina was tight an incision could be used to widen the operative field. The Percy operation was not an exploratory one. When the abdomen was opened, it was determined whether to proceed or not. Abdominal exploration was not advised. If in doubt a high amputation should be done. This would give the patient a fair degree of health and there was not the slow tedious convalescence after laparotomy.

Dr. H. P. NEWMAN of San Diego, Cal., said that in every one of these cases there was a stage at which life could have been saved by some simple procedure. Time should be spent in educating the public for early operation so as to be saved such terrible affliction. Surgeons should get back to duty and try by this means to save the mortality in malignant disease.

The Conservation of Ovaries After Hysterectomy; with a New Technique of Extirpation of the Uterus.—Dr. G. GELLHORN of St. Louis made this presentation. Normal ovaries, left behind after hysterectomy, frequently gave rise to disturbances, such as cysts, adhesions, and degeneration, due to interference with the circulation. Many operators preferred to remove ovaries and uterus. The greater part of the ovary was supplied by the uterine artery, and after the removal of the uterus the delicate tissues of the ovary could not survive the blocking of the blood supply. The venous supply was blocked and congestion was bound to occur. This interference of uterine circulation could be avoided if the incision were made within the uterus itself, leaving a shell of the uterus and the circulation unimpaired. This would conserve normal ovaries and their secretion which was of great importance to young and middle-aged patients. The operation took perhaps 15 minutes longer than hysterectomy. Very fine catgut was used in suture and the results showed that the clinical behavior of the patient justified this technique. The field of opportunity was limited as, of course, diseased ovaries should not be conserved. Exact knowledge as to the influence of endocrine secretions was lacking and if it were possible to avoid depriving the patient of the sexual glands, it was the duty of the surgeon to do so. By this method the ovarian circulation was left entirely unimpaired.

Dr. BYFORD of Chicago said that this operation belonged entirely to the experts. In regard to the endocrinology, the ovarian secretion was useful to the young, but towards the change of life it became far less so. A woman might have another 45 years of life with no need of ovarian secretion. If with the removal of the uterus the sexual function had ceased what use was there in conserving the ovarian secretion? The woman might be more of a woman to her husband, and certainly taking out the ovaries gave women queer notions but this could be overcome by reasonable advice. Women would be put to much more risk of life if this operation were general.

Dr. B. SALATICH of New Orleans said that Dr. Gellhorn preserved the lateral portion of the uterus to keep the circulation. He had implanted the ovary between the fascia and muscle, and this had given enough circulation to continue the menstrual function. Often after operation the ovary was allowed to drop back into the cul-de-sac, and the consequent kinking of the ligament interfered with the return circulation and gave cystic degeneration. The ovary should be sutured in a straight line so that no interference with the return circulation resulted.

Dr. H. P. NEWMAN of San Diego, Cal., said this was an ingenious operation but he had used a clamp for broad ligament work which did what the doctor had done. This did away with hemorrhage. In a large majority of cases only the adventitious tissue was removed. The ovary was not removed and the results were uniformly good.

Dr. MCGEE of Burlington, Iowa, asked why the doctor had worked out this technique. Had he had any bad results from removal of cystic ovaries?

Dr. G. JACK of Buffalo said he had seen several cases

where the ovaries and uterus were removed for fibroid disease in which the woman was closely bordering on insanity. Most of them could recall similar cases. Dr. Gellhorn's point was well taken. The point made by Dr. Salatich about the precautions against twisting of the ovary was essential. The ovary should be sustained by the infundibulum.

Dr. G. Gellhorn, in closing, said that he would take issue with Dr. Byford. Even if the woman was unmarried and even if she never expected to have any sexual relations, she still needed the ovaries. This was not for gratification of sexual appetite, but to be one harmonious whole entity. The removal of the sex organs in man produced profound changes and the surgeon should have one standard both for the man and the woman.

The Age of Menopause; Observations Based on Statistical Data of Eight Hundred Menopause Cases.—Dr. K. I. Sanes of Pittsburgh read this paper. The difference in the menopause age was considered in relation to a large number of factors, such as race, climate, social status, relation of age to puberty, character of menstruation, marriage, sterility, fertility, and the age of the last pregnancy. The influence of pelvic and extra pelvic pathology was also studied. Racial differences showed that Circassians had a later menopause than Indians; Indians later than Mongolians; dwellers in warm climates earlier than those in cold climates. Exceptions, however, were noted. The Austrian women ceased menstruating 5 years earlier than the Germans, although of the same race. Persian women had a menopause 3 years earlier than Armenian women; the women of Southern Italy were later than those of the North. In the 708 cases studied the average age was from 45 to 50 years. Cases which started to menstruate either very early or very late ceased to menstruate early. This was contrary to the usual impression which supposed that very early cases continued later. Cases with extra pelvic pathology such as diabetes, nephritis, gout obesity had an average age of 47 years. Obesity often went together with early menopause and evidenced hypoactivity of the sex glands. Ovarian cysts induced an early climacteric. Atrophic pelvic organs also induced this condition. The impression that early marriage produced a late menopause was not true; the later the marriage the later the menopause. Unmarried women had an early menopause. A number of pregnancies increased the menopause age. This was in accordance with theories of the influence of the Graafian follicle. The reproductive capacity of women was seldom used to the full extent and 34 years was the average age of termination of fertility. The later the last pregnancy, the later the menopause. Profuse menstruation produced a later menopause with milder symptoms. Severe symptoms were usually attendant on an early menopause. Contrary to the usual belief a sudden menopause did not produce severe symptoms. The reverse was usually the case.

Dr. C. S. Foster of Pittsburgh said that race was supposed to have a marked influence, but there were exceptions, as in the instances cited by the reader of the paper. There must therefore be some other influence at work to cause this condition. The occupational or social status must have a bearing on the question. This needed a very comprehensive study. The influence of disease on the menopause was striking. It tended to lower the age. Local disease, such as fibroid tumor, increased the age. The relation of age of marriage was contrary to the usual belief. The number of pregnancies up to 6 raised the age.

Plastic Operations in the Vagina and on the Pelvic Floor.—Dr. S. E. Tracy of Philadelphia read this paper. These operations, he said, were done to repair injury after childbirth. Makeshift operations were often done on the perineum, from lack of skill in technique. Injuries to the cervix should be carefully repaired to avoid amputation. Vaginal incision should be made at the junction of the base of the cervix and the flaps should be sufficiently long to cover the stump. When amputation was necessary the flaps were sutured over the soft tissue. The vaginal wall should never be shortened. A damaged perineum should be repaired. No one operation was a cure-all, but different techniques could be used. In complete prolapse in a young woman, a portion of the vaginal wall should be sacrificed and a colporrhaphy done. After the menopause a round ligament operation could often be done, but it was not so desirable in a younger woman. Many lesions should be treated by the vaginal and not by the abdominal route.

Dr. H. Newman of San Diego, Cal., said that this work required skill and training. No one operation was applicable to all cases. The indications were according to the needs of the patient. Trachelorrhaphy had a place in the restoration of contour. Occasionally tracheloplasty was the preferable operation, the plastic operation being done after removal of adventitious tissue.

Dr. Goldspohn of Chicago said that repair of the cervix was an important prophylactic act in regard to what might happen to the woman at menopause. Malignancy might occur then and give a high mortality. Cervical cancer later arose from the Nabothian follicles and these must be removed. In elderly women the danger of miscarriage was less than that of cancer. Laceration of the cervix was not always pathological. It occurred with every first labor. A little slit was not a pathological affair. Induration of the cervix constituted pathology. Amputation should be done rather than trachelorrhaphy. The interposition operation was not necessary and should not be inflicted on a woman.

Dr. Tracy, in conclusion, said that one must get rid of pathological tissue and restore function and contour. He did not believe it wise to dissect the levator muscle unless the fascia was sutured. A small laceration did not need operation. Induration needed attention. The repair of the cervix should put it as near normal condition as possible. The cases must be carefully selected to get the best results. The public must be educated in order to reduce the mortality from malignancy.

THE TREATMENT OF DUODENAL ULCER.*

BY G. REESE SATTERLEE, M.D.,

NEW YORK.

BEFORE describing the treatment of duodenal ulcer, it seems advisable to give a brief outline of the diagnosis of these cases. We will deal principally with chronic ulcers.

Diagnosis.—Pain is the most constant symptom, and is usually localized in the right hypochondrium. Referred pain is experienced in the epigastrium or intercostal regions. The occurrence of the pain is usually from two to six hours after eating, but it is sometimes constant. The pain is often intermittent, lasting for a month and then subsiding for a few weeks. The character of the pain is usually acute and spasmodic when the ulcer is situated near the pylorus, and there is a dull ache in the duodenal region during the interval. The patient is always conscious of "something wrong" in this region. Backache is also very frequent. There is usually soreness or tenderness localized in the right hypochondrium. The pain is often relieved by small amounts of food or alkalies and is increased by acids, acid foods, meat, and large meals.

Digestive disturbances. Nausea during the attacks of pain, and sometimes vomiting, are present, and characterized by intermittency of symptoms. When the ulcer is actively bleeding, hematemesis and dark, bloody stools, or occult blood in the feces, occur. Only a few of the cases show these symptoms. Flatulence is nearly always present, but constipation is variable.

Toxemia. This form of toxemia seems to be peculiar to duodenal ulcer. It is different from the toxemia so common in lesions of the colon, and does not respond to the same remedies. It is due probably to a septic absorption from inflammatory exudate at the base of the ulcer, through the lymphatics, combined with the biochemical products from the duodenal epithelium, first noted in Draper's experimental work. The resulting symptoms are slight chilly sensations, brief rises in temperature, and mental depression. Small lesions in the sensitive duodenum give rise to severe general disturbances, as are evidenced by the disturbance following rough handling of this delicate organ at operations.

The coincidence of duodenal ulcer and appendicitis in the same patient is so very frequent that we cannot but pay attention to cause and effect in these two conditions. We might justly add to our list of symptoms those of chronic appendicitis. We must not only make our diagnosis very conservative, but we must also be very thorough at the time of operation.

When the ulcer is situated adjacent to the pylorus, pyloric stenosis, with its familiar train of symptoms, may result. This condition is nearly always of long duration, begins with the characteristic symptoms of duodenal ulcer, and then, as the pylorus becomes stenosed, the symptoms of a chronic dilated stomach appear. Very frequently no severe gastric symptoms are present, but emaciation is progressive. In severe cases there are marked epigastric distress and pain, gastric flatulence, hunger pains, and vomiting of large amounts of accumulated food, emaciation, and usually constipation. It is amazing, however, to see how much these patients will stand, and very frequently they do not consult a doctor until late in the disease. From the findings in the cases that have come under my observation most of the ulcers causing pyloric stenosis have started orad to the pyloric sphincter.

Physical examination of patients with duodenal ulcer usually shows well-nourished individuals with no evidences of gastric dilatation. Tenderness is generally present in the right hypochondrium over the duodenum. Tender points are frequently found along the lower intercostal nerves and a localized area of tenderness in the tenth intercostal space to the right of the vertebra. In gastric ulcer, the area of tenderness is often to the left of the spine, but there is no inflexible rule. This involvement of the intercostal nerves can be explained by the connections of the celiac plexus of the sympathetic and the intercostal nerves. More frequently, however, the cause must be attributed to the effect of a general toxemia on the whole nervous system.

The facial expression is often quite characteristic. As a result of the long-continued pain and distress, the face has a drawn, anxious expression, with a deepening of the lateral furrows, deepened and darkened eye sockets, and a toxic duskiness of the skin. The tongue may be only slightly coated, unless there is an accompanying gastritis and intestinal toxemia.

The true diagnosis often cannot be made until the *x*-ray examination is made. The characteristic findings are filling defects, irregular outlines, residues in the duodenum, and spasms of the pylorus. Great care must be exercised in differentiating these spasms from reflex ones due to lesions in other parts of the gastrointestinal tract. Occasionally the *x*-ray findings are more positive than the inspection during laparotomy, as in case of W. H. P., reported in this paper. A small defect in the duodenal cap was noted in the plates and fluoroscope examination,

*Read before the American Therapeutic Society at the annual meeting at Richmond, Va., June 8, 1918.

both before and after operation. Search for a defect was made during laparotomy, but none found, and the spasm and pain in this region still persist, so that we can be reasonably certain about the diagnosis. Hyperperistalsis of the stomach and duodenum, with rapid motility, are strong contributing factors in diagnosis. The value of gastric test meals is often doubtful. Hyperchlorhydria is often present, but normal or subnormal acidity is about as frequent. Ingestion of dilute hydrochloric acid is of little value.

The duodenal tube should be used, and may be of distinct service in the diagnosis. Its value is twofold: (*a*) From the examination of the aspirated duodenal contents, showing, perhaps, pus and blood; and (*b*) as an aid in the visualization of the duodenum. In some instances, when the rapidity of the passage of the bismuth or barium does not permit of proper visualization, irregularities may be demonstrated with the tube in situ, and filled with barium. It must also be remembered that there may be apparent deformities in the duodenal cap during the first few minutes after the ingestion of the bismuth or barium meal, due to the early slow and imperfect passage of the stomach contents through the duodenum. This mistake can be rectified by continuing the study for twenty minutes. Radiographs taken within the first ten minutes, and showing such defects, should always be interpreted cautiously. In one of our patients (M. G.), dilatation of the duodenum was the only finding, and operation revealed a large duodenal ulcer.

The string test is sometimes of value and simple, but the results are sometimes misleading, for it must be remembered that blood stains or blood are not always conclusive of ulceration. It is of value, however, as contributory evidence.

Treatment.—In order to treat duodenal ulcer intelligently it is necessary to bear in mind all the diagnostic points and the site of the lesion. It is fortunate that lesions in the duodenum are very rarely malignant, so that we can consider the process as benign.

The treatment should be considered under two heads: (*a*) Palliative, and (*b*) curative. Palliative treatment may also be curative, although all these patients should be considered surgical risks. Medicine and surgery share equal responsibility. Those men who claim that the majority of duodenal ulcers can be cured by medical means have probably had a good run of luck, but the teaching is pernicious. On the other hand, operation may also fail of a cure. Syphilitic ulcers may respond to antisyphilitic treatment, but positive Wassermanns and presence of tuberculosis do not exclude operative measures. The essentials in medical treatment are: (*a*) Diet, (*b*) rest, (*c*) drugs, and (*d*) duodenal lavage and local measures. In order to obtain success with a diet it is necessary to combine it with rest in bed. Many modifications of the famous Lenhartz diet have been made, but the formulæ should be flexible, in order to suit the individual. The first ten days should have a rigid diet of milk, eggs, or egg albumen, with frequent feedings. After that the diet can be gradually increased, and then a list of foods which are well borne should be given the patient.

The author will omit the minute details of diet, as these are boresome. In general, the articles of diet which are usually well digested and non-irritating are: Milk, sweet or fermented; egg albumen, rennet, cooked fruit of the non-acid type, stale bread or toast, butter, cream, thoroughly cooked vegetables, especially the green ones, and the light cereals, particularly strained oatmeal gruel. The foods usually contraindicated are: All kinds of meat and fish, acid fruit and raw fruit, vinegar, spices, large amounts of sugar, the heavy, starchy vegetables, as potatoes, lima or baked beans. Articles containing large amounts of cellulose and bran are not contraindicated, and are very useful to combat constipation.

Drugs. Alkalies are always useful, and apparently necessary in many cases. Of these, bicarbonate of soda is the best, and the magnesia preparations next. Bismuth subnitrate combined with heavy magnesium carbonate, in varied sized doses, will give temporary relief in nearly every instance. Hot water or milk, with bicarbonate of soda, is also extremely useful. The time to administer these alkalies is from two or four hours after meals and during the night. They should not be regarded as curative, but palliative only.

For the attacks of pain, some of the preparations of opium may be necessary to give relief; of these, tincture of opium and camphorated tincture of opium are the best. Morphine, hypodermatically, may be used when gastric irritability is too great, but is not as satisfactory as the opium preparations. Orthoform has a better effect on gastric than on duodenal ulcers; its usefulness in duodenal ulcers is of doubtful efficacy.

I have been using benzyl benzoate for the relief of pylorospasm and the consequent pain, with excellent result in one patient with duodenal ulcer. It has been recommended by Dr. David I. Macht of Baltimore, and said to be harmless as to habit formation. Complete relief was experienced by this patient in one-half to one hour, followed by a refreshing sleep. The relief was as pronounced as that from opium, but the effects two months later, according to the last reports, were not so good, and obtained only by larger doses. Operative measures will probably be necessary. Adrenalin hypodermatically has been reported on favorably by Dr. Charles G. Stockton, who obtained relief in four out of six cases. He used injections of 1 c.c. of a 1 to 1,000 adrenalin solution. As benzyl benzoate and adrenalin are supposed to have the same physiological action on smooth muscle, relieving spasm, their use should be logical.

Local application of cold or heat to the abdomen is of some value, and should be used.

The use of the duodenal tube. The duodenal tube is left in the stomach over night, and benzyl benzoate given if pylorospasm occurs. The following morning, on an empty stomach, the duodenum is washed out with plain hot water or soda solution. This is followed by instillations of silver nitrate, 100 c.c. of the strength of 1 to 20,000, up to 1 to 1,000, or 20 per cent. argyrol. The symptoms are relieved by this method, but care should be taken not to leave silver nitrate solution in the stomach, which should be aspirated before removal of the tube. The patient can follow up this treatment at home. In some patients, where the hydrochloric

acid content of the gastric contents is deficient, administration of hydrochloric acid has given good results, demonstrating the fact that pain is not always caused by this acid. On the other hand, large amounts of alkali may interfere with digestion.

Accompanying enteroptosis, constipation, and intestinal stasis must always be properly cared for. A large number of these cases are mistaken for gastric or duodenal ulcer, as the symptomatology of a residual stomach is very similar to that of ulcer.

Duodenal ulcer should always be regarded seriously, as the danger of perforation is very great, and delay in operative procedures may be fatal. Dr. C. L. Gibson has well described the symptoms of perforation as "very sudden, sharp pain in the epigastrium, faintness, or even collapse, abdomen becoming boardlike, retracted, and exquisitely sensitive to the touch. Vomiting at the beginning may or may not occur, and vomiting of blood is very exceptional." Operative treatment and repair of the ulcer, with or without gastroenterostomy, is imperative.

There are a variety of opinions as to the advisability of operation in the chronic cases. As a rule, we find the medical man inclined to treat them medically and the surgeon surgically; that, perhaps, is natural, as we all do that in which we are most proficient. It is to the internist, however, that we must appeal for advice, and he must be unbiased. Our opinion must be formed only after close observation of our operative and non-operative cases.

Of thirteen operations performed by Dr. J. W. Draper (personal communication), ten gave uniformly good results. First, in regard to the failures: Dr. Draper states that in the first place this operation has often been done either when no operation at all has been indicated, or when extensive resection of the right colon, developmental reconstruction, should have been done in its place. Again, the indications for the operation may have been clear, but the technique of its performance has been faulty. There is no way open for the practical elucidation of these problems equal to that of careful clinical observations on postoperative cases. Draper, in this study of thirteen cases, finds that two—in which he and Lynch subsequently performed the operation of developmental reconstruction of the colon—had undergone gastroenterostomy nine and twelve years respectively prior to the colonic resection. There had been, naturally, no improvement, but rather a clinical impairment, since the cases had not been suitable ones for gastroenterostomy, and this in spite of the fact that in each case, after *this lapse of years the stoma was found to be open and functionating.* The removal of a severely infected ceco-colon, in which, because of impaired epithelium, there were large amounts of subepithelial pigment, promptly cured these cases. These are striking examples of the need of careful preoperative study, so that such disastrous surgical errors in diagnosis may be avoided. In one case, the ulceration extended orad to the pyloric vein, and necessitated, therefore, a pylorectomy. Cancer cells were found in the overhanging margins of this ulcer, and as the gastroenterostomy following resection has functionated well, it was probably the operation of choice.

The remaining ten cases have given uniformly good results because they were done for more or less extensive duodenal ulceration, which had persistently refused to heal under modern medical treatment. The incidence of accompanying appendicitis is very large, no less than 90 per cent. in this series; five, or 50 per cent., had undergone simple appendectomy at least one year prior to the gastroenterostomy. The relation between cause and effect here is very significant.

One in which a pyloric resection was done required four operations before final cure, two successful stomata being established, only to be obliterated by inflammatory tissue. This patient has gained sixty pounds since the last operation, fourteen months ago. Competent men considered this case carcinoma, because of the massive glandular enlargement. All this has disappeared since the last operation.

Draper regards it as essential that Hartmann's advice be followed regarding the position of the stoma as close as possible to the pylorus, and at a point where the stomach can be cut directly across from the greater to the lesser curvature. His experimental studies upon animals corroborate his clinical findings as to the very great importance of this technical point.

I should like to quote in detail the case history of a typical small duodenal ulcer which showed definite *x*-ray findings, but could not be located at operation. It is also a good illustration of what medical treatment can accomplish.

W. H. P., male, 50 years, druggist. Patient was formerly a rapid and heavy eater and did not masticate properly. He was first seen six years ago, when he had complained for a year and a half of flatulence and eructations, the symptoms being worse at night. He had to sit up in bed with pain in the stomach and intestine; the pain was also worse when working, so that he had given up business. The bowels had been irregular for six months and he had been taking a purgative water and sodium sulphate regularly. The stools were constipated, whitish for a while, and covered with mucus. There had been loss of weight. At that time gastric analysis showed free HCl 37, combined HCl 17.75, organic acid and acid salts 45.25, no blood, no lactic acid. Radiographs showed normal stomach and intestinal stasis. Stools showed blood-streaked mucus, and the diagnosis was chronic colitis and constipation. He went to work on a farm and gained fifteen pounds. An abdominal belt for enteroptosis had also helped him. The pain continued, however, and one year later there was tenderness over the appendix.

Six months later he complained of pain starting in the right hypochondrium and traveling to the left side, lasting for eight hours and relieved by opium, ten minims of laudanum or ¾ grain of codeine. The pain would occur at night or early morning. No diarrhea, constipation nor mucus. The cecum crepitates. Colon irrigations were made.

Eight months later, January, 1917, there was a tender spot in the region of the gall-bladder and the pain in the upper abdomen still necessitated opium. String test was negative. He had attacks of food retention in the stomach. Orthoform relieved at times, but not nearly so effective as opium. Gastric contents showed free HCl 10, combined HCl 12, organic acid and acid salts 11, and total acidity 33.

In February, the next month, he had two bad attacks lasting twelve hours with food residues. I saw the patient at midnight, when he showed distinct pain, tenderness over McBurney's point, and right rectus rigidity. Gastric contents then showed free HCl 53, combined HCl 8, organic acid and acid salts 14, and total acidity 75.

Careful studies of gastric radiographs at this time showed a slight filling defect in the first portion of the

duodenum, close to the pylorus. Stasis, no ileal delay, no outline of appendix and no gallstones.

Dr. J. M. Lynch operated February 16, 1917. Appendix was very long, fibrous and bound at tip to terminal ileum. The proximal portion was dilated and acutely congested. The ascending colon was adherent by partial elbow adhesions to the liver. The adhesions were cut and the appendix removed. Gall-bladder, stomach and duodenum were normal, especial care being taken in examination, as duodenal ulcer was suspected. Constipation became severe after operation and there was a nephritis which cleared up. This decided us to be cautious about any further operation. Two months after the operation the patient was in excellent condition and had no pain.

One year later, February, 1918, patient had gained 19 pounds, but pain had returned last September with his old complaint of "formation of gases." Again he had to resort to opium and lost weight. The character of the pain was about the same as before and from two to three hours' duration. He had a tight sphincter ani and congested, dusky rectal and sigmoid mucosa. He had one slight attack of obstipation. Gastric contents showed free HCl 34, combined HCl 00, organic acids and acid salts 19, total acidity 43, bile present, lactic acid absent. Fluoroscope showed small active stomach, nearly empty in one hour. Pylorospasm was also demonstrated as seen in the lantern slides and also a small filling defect in the first portion of the duodenum. Tenderness in the duodenal region. He is taking small amounts of alkalies.

The duodenal tube was inserted over night, and the duodenal contents showed no blood, occult or otherwise. Duodenal lavage with hot soda solution.

This was followed by four days free from pain, the longest interval since September, 1917. The duodenal tube was inserted once or twice a week with lavage, followed by 100 c.c. of silver nitrate solution, beginning with 1 to 1000, which was left in, care being taken to aspirate any of the solution left in the stomach. The severity of the pain was gradually lessened, the intervals between attacks lengthened, with marked improvement in six weeks. The diet consisted of three eggs, milk one quart, strained oatmeal, cream, six slices of bread, stewed prunes and postum. Patient was not confined to bed, but rested and went to bed early. For the attacks of pain, benzyl benzoate in the following formula, as recommended by Dr. David I. Macht of Baltimore, was given: Benzyl benzoate 20 mils, alcohol 95 per cent. 80 mils, oil of peppermint 2 mils. Sig. Twenty drops in cold water once or twice a day. Relief from the pain and spasm was experienced in ¾ hour and complete in one hour. The diet was increased by the addition of arrowroot and tapioca. The patient stated that the relief from the benzyl benzoate was as complete as that from opium without disagreeable after-effects. The patient then went home and reported that the pains had recurred with some severe ones which were not relieved by the benzyl benzoate.

For two months the patient has been practising duodenal lavage every two days, and leaving in ½ ounce of 20 per cent. argyrol solution. The tube now enters the duodenum within an hour.

He was seen on May 31. The tenderness over the duodenum had disappeared and for one month there had been no pylorospasm attacks, the pains complained of being due to a constipation and colon spasm, caused probably by the constipating diet and flatulence. A more laxative diet was substituted, with bran, green vegetables, nuts, etc., and the duodenal lavage was continued. He has improved very much.

Conclusions.—1. Duodenal ulcer needs a careful differential diagnosis from gastric ulcer, as the prognosis and treatment are distinctly different from those in the latter.

2. The treatment of duodenal ulcer is usually medical and surgical; neither side should be neglected.

3. Under medical treatment, rest, and duodenal lavage and medication should be tried.

4. Operation is indicated in severe cases.

5. No-loop gastroenterostomy, after the method of Hartmann, should be done where possible.

6. The operation of gastroenterostomy may be useless if diseased conditions in the right iliac fossa are not rectified by removal of adhesions, kinks, cecocolon, etc.

7. In all operations for chronic appendicitis the right hypochondrium should be carefully inspected for evidence of duodenal ulcer, as the two conditions are closely associated.

8. Expert radiography, with fluoroscopy of the gastric and duodenal region, are essential, and sometimes of more value in diagnosis than simple inspection at operation.

125 West Fifty-eighth Street.

TREATMENT OF INTESTINAL STASIS BY DUODENAL LAVAGE.*

By CHARLES D. AARON, Sc.D., M.D.,
DETROIT, MICH.
PROFESSOR OF GASTROENTEROLOGY IN THE DETROIT COLLEGE OF MEDICINE AND SURGERY.

The torrent of literature which has been poured out in recent years on the seemingly interminable subject of intestinal stasis is so vast and contradictory as fairly to bewilder the conscientious reviewer. While we all know what intestinal stasis is, as a profession we disagree about practically everything but the definition. In the pathological picture which the term involves, what is cause and what effect? It is a vicious circle, with a vengeance. A veritable legion of ailments is associated with the center of contemplation—the torpid bowel. Is the bowel the real culprit, or is it the goat? While one group of writers believes that a wrong and ill-assimilated diet is the principal cause of the stasis, leading in turn to numerous other complaints, another group holds the opposite view, and blames some anomaly of intestinal position for the malassimilation of the food and the consequent gamut of pathological possibilities. The proposed treatments differ, as a matter of course, as widely as the etiological views. While some would confine the treatment to medication, pure and simple, except when surgery is unmistakably indicated, others incline to the Biblical injunction to remove the offending member, and, on the assumption that even remote skin diseases are directly or indirectly due to intestinal kinks, membranes, adhesions, and bands, would fain anastomose the ileum with the sigmoid for the purpose of growing hair on a devitalized scalp.

While the experienced physician—who treats each case on its merits, instead of resorting to routine measures—finds intestinal stasis, with its associated pathological conditions, fairly amenable to indicated remedies, the fact remains that he must be content with having alleviated individual distress in a given case without having been able to solve the general question.

The addition of yet another method of treatment may therefore be viewed from two different angles: it may be considered a step in the wrong direction by those who flatter themselves that their own pet methods meet all the requirements, or it may be hailed with delight by those who have convinced themselves of the fatuity of medical and surgical endeavor in a large number of intractable cases.

*Read at the annual meeting of the American Therapeutic Society at Richmond, Va., June 7 and 8, 1918.

The title of this paper indicates that the new method to which I refer is duodenal lavage.

This method of treatment has several advantages, even in the improbable event of its not effecting the object intended: it is harmless, it does not mutilate or injure the anatomy, it will not in curing one pathological condition bring about another worse than the original; it will have a beneficial effect upon the intestine even if, in obstinate cases, which have yet to be determined, it should fail of its whole purpose. It is not the outcome of a fine-spun theory but the result of sober reflection, practical experience, and repeated application. The treatment may be given in the office, does not require detention at the hospital, and does not interfere with the daily occupation of the patient.

In cases of intestinal stasis associated with an obstruction, such as kinks, bands, and adhesions, I have found that clearing out the whole of the intestine from above the obstruction will give the bowel an opportunity to recover tonicity sufficient to overcome effectually the stasis. If there happen to be adhesions, compensation takes place in some way or other, and recovery is the result. The kink may remain the same, but the patient recovers his health, which, after all, is the practical object of any treatment in any condition. As long as normal motility is not interfered with there is absolutely no indication for surgical intervention. Lavage restores normal physiology, and if they are right who assert that the duodenum excretes a poison which is responsible for a great deal of the toxemia from which the human race suffers, then lavage, according to the method I am about to describe, is the remedy to remove the poison.

The immediate result in all of the cases I have so far treated, or which are still under treatment by this method, has been uniformly good, and the details of the clinical histories are therefore unimportant for the purposes of the present paper. I admit that all are recent cases, and that I cannot speak of end results until after a lapse of years; but in view of the fact that the immediate results have far exceeded all expectations, that, so far, no relapses have occurred, and that even in the event of a relapse no harm whatever is done and the treatment can be repeated, the patient having meantime enjoyed a long interval of good health, I consider myself warranted in strongly urging the adoption of duodenal lavage in all appropriate cases. I am convinced from the results obtained that in the majority of cases of intestinal stasis, duodenal lavage, as practised by me, will do all that surgery can do, and do it better, since it does not entail a train of possible deformities and their consequences.

The technique I have worked out and adopted is as follows:

While any of the many duodenal tubes can be employed, the instrument I now use is the duodenal tube of Jutte. The tube measures only one-sixteenth of an inch in external diameter, and is provided at the lower end with a small olive-shaped lead sinker, with perforations in the tube above. With a little practice the tube can be easily manipulated to insure its arrival at the pylorus, whence it is carried by peristalsis into the duodenum, with the patient lying on his right side. The pylorus should be patulous, and it is necessary, therefore, to undertake the proceedings on an empty stomach. By any of several well-known tests we can ascertain whether the sinker has arrived in the duodenum, and as soon as it has lavage may be begun.

Since Jutte's object in using his tube is the cure of a variety of ailments, he varies the composition of his solution accordingly, but I have found that for the treatment of intestinal stasis in general the best solution is 30 grams of magnesium sulphate and 60 grams of sodium sulphate in a liter of water. The lavage is given daily for ten days, as a first series of applications; then, on alternate days, for another ten days; and the third series follows at intervals of three days, the number of treatments given in this last series being only three or four. Although by this time success is fairly certain, I have made it a practice to continue with one lavage a week until recovery is fully established. There are no unpleasant by-effects, and patients will tolerate the treatment for any length of time without discomfort.

There has not been a single failure in any of my cases in regard to the clinical cure of intestinal stasis, and incidentally also of constipation, although the anatomical conditions of kinks and adhesions remain unchanged. From this positive fact several obvious conclusions may be drawn. The first is that kinks and bands—which, indeed, have been pronounced physiological by some authors—are not necessarily the cause of intestinal stasis, and that, consequently, their surgical removal will not cure the stasis. Another conclusion is that any other pathological condition—rheumatoid arthritis, gout, functional disorders of the heart, arteriosclerosis, epilepsy, asthma, cirrhosis of the liver, primary and secondary anemia, skin diseases, catarrhal inflammation of the mucous membranes, eye diseases, neuralgia, neuritis, insomnia, neurasthenia, melancholia, dementia, and insanity—should disappear after successful duodenal lavage treatment, if these conditions are really caused by intestinal stasis; and if they do not disappear after the supposed causative factor has been removed, it follows that the etiology requires correction—that these conditions were not, after all, due to intestinal stasis.

How far and in what way these conclusions will be supported by the final results of duodenal lavage, adopted on a wide scale, it is too early to state. Inasmuch as the intended clinical result, the removal of intestinal stasis, is fully assured by this method, its general adoption is to be hoped for, so that the combined observations of the profession in regard to incidental results in the improvement of other pathological conditions may be used as a basis for formulating a therapy for affections which have hitherto been more or less obscure.

812 Kresge Building.

Food Conservation in Switzerland.—The Swiss Medical Commission reported in February that on account of the alarming food shortage no more barley, maize, rice, or other staple be utilized for brewing. The distillation of cherries, plums and grains, the manufacture of cider drinks from fruits and wine from grapes should be restricted as much as possible. Bars should be allowed to keep open only four hours daily, two each half of the day.—*Revue Médicale de la Suisse romande.*

THE SERUM AND VACCINE TREATMENT OF THE PNEUMONIAS.*

By FRANCIS E. STEWART, M.D., Phar.D.,

PHILADELPHIA, PA.

THE old classification of pneumonias as lobar pneumonia and bronchopneumonia is giving place to a new classification, namely: pneumococcus pneumonia, streptococcus pneumonia, and mixed pneumonias in which both the pneumococcus and streptococcus, and sometimes other microorganisms take part. Attention should be directed to the excellent work done at the Rockefeller Institute in regard to types of pneumococci and their specific etiological relations to the pneumococcus pneumonias. The serum treatment of the pneumonias and the possibility of immunizing troops and civilians against the pneumonias should be considered.

The work of medical scientists and the results of their findings in this connection will prove far reaching in the practice of pneumonia prophylaxis and treatment. More attention will be given to the future treatment in hospitals where laboratory facilities are conveniently at hand. The tendency in the cities and towns will be for the general practitioner to transfer pneumonia patients immediately to the hospitals when it is possible to do so. As for the country doctor, situated remote from medical centers, the question, what shall he do? is a most interesting subject.

A general practitioner from the country district may well ask: "How is a physician engaged in country practice and not provided with proper laboratory facilities to determine whether his patient has a pneumococcus pneumonia or a streptococcus pneumonia, or is suffering from a mixed infection?

"You advise the country physician to send a specimen of sputum to a medical center for bacteriological diagnosis. This advice I do not consider of much value. Pneumonia is a treacherous and uncertain disease. A patient may be taken mildly ill with every reasonable expectation of recovery, yet may die suddenly and unexpectedly. If the doctor is forced to wait two or three days for a bacteriological diagnosis, the chances of recovery from a serious disease, that in its usual course terminates in from five to nine days, are reduced to a minimum.

"You say that the fundamental principle of treatment, in the light of present knowledge, is to inject promptly anti-pneumococcic serum intravenously in all cases of pneumococcus pneumonia, whether mild or severe, and give doses sufficiently large early in the treatment of the case to destroy completely the infecting microorganisms and neutralize their poisons. But how is the general practitioner, located in the country remote from medical centers, to know whether his patient has pneumococcus pneumonia or not?

"You also tell me that there are several types of pneumococcus; also, that there are several types of streptococcus; therefore, there are several types of pneumococcus and streptococcus pneumonias. Should a specific serum be used for each type of pneumonia? Or is the proper procedure to give the patient a polyvalent antipneumococcus serum, and a polyvalent antistreptococcus serum conjointly?

"I confess that the condition of my mind seems to be one of confusion worse confounded."

The dilemma of the country practitioner is typical of that of many practitioners in country practice all over the land. What can the American Therapeutic Society do to aid the country doctor in this dilemma? As an aid to the discussion of the subject a brief review of some points in regard to the etiology and treatment of the pneumonias, resulting from researches in this country and abroad, may prove serviceable.

We are indebted to Avery, Chickering, Cole, and Dochez for their researches conducted at the Rockefeller Institute, which have demonstrated that at least three types of the pneumococcus cause pneumonia. Furthermore, pneumonia may be caused by several other kinds of microorganisms, as we all know.

The pneumonias caused by Types I, II, and III, including group IV which possibly includes twelve or fifteen other types, vary in frequency, in severity, and in response to serum treatment.

In regard to the incidence of various types of the pneumococcus and the resulting mortality, the following table and explanatory statements are taken from the "Monographs of the Rockefeller Institute for Medical Research" No. 7, page 733.

Incidence of Various Types of Pneumococcus and Resulting Mortality

Type of Pneumococcus	Incidence, Per Cent.	Mortality, Per Cent.
I	33	25
II	31	32
III	12	45
IV	24	16

"The statistics given in the above table approximate the facts as closely as they can be ascertained at the present time. Organisms of Type IV have in our experience been found to possess the lowest virulence of the different types for human beings. Type III pneumococcus, although it is the cause of the smallest percentage of cases, nevertheless gives rise to a high mortality and the outlook for a patient infected with Type III pneumococcus is comparatively bad. Pneumococci of Types I and II are responsible for about 64 per cent. of all cases of lobar pneumonia and are of relatively high virulence for man, the largest number of deaths in lobar pneumonia being due to these organisms. The mortality in Type I infection is 25 per cent. and in infections with Type II pneumococcus about 32 per cent. These two types together are responsible for approximately 62 per cent. of all deaths from lobar pneumonia. It is evident, therefore, that the outcome of any case of lobar pneumonia is influenced by the type of organism with which the individual is infected, and knowledge of the type of pneumococcus causing the infection is therefore of value in prognosis. It must be borne in mind, however, that there is considerable variation in the severity of the individual cases due to the different type of pneumococcus."

The following editorial statement occurs in the department of therapeutics, *Journal of the A. M. A.*, Feb. 9, 1918:

*Read at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

The serums against infection with Type I organisms appear to have produced especially good results, and to be highly effective in treatment of cases of pneumonia due to its type of organisms. The serum of Type II is much less efficacious and, indeed, it has not yet been thoroughly demonstrated whether it has any valuable effect on the outcome of disease. The serum for Type III organisms has apparently but slight therapeutic power and has not been considered worthy of use in infections with this organism. The same is true with infections with Type IV pneumococcus. Commercial preparations of these serums are available and also polyvalent serums. These polyvalent antipneumococcus serums are of extremely doubtful value. It has been suggested that polyvalent serum be given until the type of the organism is determined, and that following this the specific serum for Type I or Type II may be utilized if the infection proves to be of that character. . . . It has also been suggested that every pneumonia patient receive, immediately after being taken to a hospital, a large dose of antipneumococcic serum of Type I, with the idea that the case may prove to be of that character and considerable time will be gained. . . . The serum treatment of pneumonia with Type I serum is quite likely to be harmful because the intravenous injection of 100 or more cubic centimeters of horse serum can hardly be devoid of harm, and is certainly not to be used except when very decided benefit may be expected to follow its use.

I am calling attention to the latter statement because the editorial writer was evidently not posted in regard to the chemical composition of antibacterial serums in general. Polyvalent serum and Type I serum are practically identical, the only exception being that the former contains antibodies against Types I, II, and III pneumococcus and the latter antibodies to Type I only. Moreover, polyvalent serum contains the same amount of antibodies against Type I pneumococcus as Type I serum.

Polyvalent serum, therefore, if properly prepared, has exactly the same specific action against Type I infection as Type I serum has, and it also possesses immunizing properties against the other types of the pneumococci, in so far as the antibodies against these types are effective in combating Types II and III. It is true that whenever any one of these serums is employed "100 or more cubic centimeters of horse serum" are injected. But the writer of whom the editorial speaks, advises routine injections of Type I serum before waiting for type diagnosis, and, therefore, advises the injection of "100 or more cubic centimeters of horse serum" containing antibodies against Type I pneumococci, before waiting for type diagnosis. The advice in regard to the immediate use of serum treatment without waiting for type diagnosis, for the purpose of saving time, is good advice, and if the physician uses polyvalent serum containing antibodies against Types II and III, pneumococci, he is not only following that advice, but he is possibly giving his patient even better service than though he had only injected Type I serum. In either case he is forced to inject "100 or more cubic centimeters of horse serum" for he cannot administer the required dose of antibodies without so doing, whether he uses Type I serum or the polyvalent product.

Both Type I serum and polyvalent serum are being supplied by the large producers so that physicians may take their choice between them. There is no special reason why the producers should prefer to advocate the use of either one in preference to the other. The choice lies with the physician, but it would seem to me more logical to use standardized polyvalent serum than the Type I serum.

In the opinion of prominent army surgeons, with whom I have talked, the use of polyvalent serum possessing antibodies to Types I, II, and III, serves a better purpose than the employment of Type I serum, because it produces more or less immunity to re-infection.

Owing to the fact that observations of these army men were imparted to me in confidence and have been incorporated in their official reports, which are in the hands of the Surgeon General, and which have not yet been published, I am, of course, not permitted to use their names.

But, in the light of recent reports received from Fort Sam Houston, Camp Travis, Camp Oglethorpe, and other army posts, it is far more important to find out whether the patient is the victim of pneumococcus or streptococcus pneumonia, or is suffering with a mixed infection, than it is to determine the type or types of organism responsible for the condition.

Fortunately, it is not necessary for the country doctor to secure a bacteriological diagnosis before resorting to serum or vaccine therapy in the treatment of pneumonia. Nearly all that can be obtained from serum treatment is possible to secure by conjoint use of polyvalent antipneumococcus and antistreptococcus serums. Accuracy in diagnosis and treatment may require laboratory facilities, but the country doctor, who is not in a position to avail himself of such service, need not let his patient die for the want of it. The most important thing to remember is the necessity of prompt action and the use of large initial dose (100 c.c.) and repeated injection, for the purpose of destroying the infecting microorganisms, neutralizing their toxins, and keeping the blood sufficiently loaded with antibodies to prevent reinfection.

The Serum Treatment of Streptococcus Pneumonia.—Now in relation to the serum treatment of streptococcus pneumonia, the light shed on the subject by the researches carried on at the Base Hospital, Fort Sam Houston, San Antonio, Texas, is quite illuminating.

The first report of these researches appeared in the *Journal of the A. M. A.*, April 13, 1918, in a paper entitled "The Pneumonias: Streptococcus and Pneumococcus Groups," contributed by James G. Cumming, M.D., Major; Charles B. Spruit, M.D., First Lieutenant, both of the Medical Reserve Corps of the United States Army, and Charles Lynch, M.D., Colonel, Medical Corps, United States Army and Department Surgeon. This report followed a conference of medical officers from Fort Sam Houston and Camp Travis, held Jan. 13, 1918, for the purpose of considering the pneumonia situation. Various points in the determination of the causative organism in pneumonia following measles were considered, methods of procedure were suggested, and the laboratory force was organized to take up the work. A preliminary report was sent to the Surgeon-General of the United States Army, Feb. 7, 1918. The paper contributed to the *Journal of the A. M. A.* consists of a part of the original report, together with additional cases and comments.

Of patients with pneumonia following measles, 28 blood specimens in all were tested. Of these, 24 were negative while 4, or 17 per cent., were positive for hemolytic streptococci. In the series of necropsies reported, a much larger percentage of

the specimens were positive. Of the 61 examinations of pleural exudates from patients in the pneumonia wards, organisms were found in 48 specimens. Of 41 lobar pneumonia specimens, 59 per cent. proved to be pure streptococcus, and 41 per cent. pneumococcus. Of 7 bronchial pneumonia specimens, 86 per cent. were streptococcus, and 14 per cent. pneumococcus. By consolidating these two groups, the authors found that 63 per cent. were hemolytic streptococci and 37 per cent. pneumococci. In the 31 necropsies, streptococci were isolated from 21 lung specimens, 22 pleural exudates, 14 pericardial exudates, and 15 hearts' blood specimens. The streptococcus was isolated in each of the 24 bronchopneumonia cases. Of these 24 cases, 18 or 75 per cent. are known to have followed measles. In only one necropsy on a patient that had had pneumonia following measles was a type epidemic pneumococcus found, and this was coexistent with the hemolytic streptococcus; while in the 7 lobar pneumonia cases, hemolytic streptococci were found, either in pure culture or coexistent with pneumococci, in 5, or 71 per cent., of the necropsies.

The authors state: "It would appear that the hemolytic streptococcus was the cause of death in 29, or 94 per cent., of the 31 cases of lobar pneumonia included; and since this organism was found in entirely pure cultures in all lung specimens, as well as in pure cultures in either serous exudates or the hearts' blood or both, in cases of pneumonia following measles, it may be concluded that the hemolytic streptococcus is the causative organism in this complication following measles; moreover, that it was the immediate cause of death in a large percentage of the so-called lobar pneumonia cases."

The authors conclude that on account of the unquestioned prevalence of streptococcus pneumonia, both as a complication of measles and as coexistent with lobar pneumonia, it is apparent that a new differential procedure for type identification must be devised. In none of the lobar pneumonia cases which at necropsy showed both pneumococci and streptococci, had an ante-mortem diagnosis of type epidemic pneumococci other than Type IV been made.

Because streptococci were found in 55 per cent. of the cases, because mortality from infection by the streptococcus is high in the so-called lobar pneumonia cases, and because the streptococcus has not heretofore been recognized as an important factor in the pneumonias, the authors consider the identification of this organism in the sputum of great importance in determining the proper therapeutic treatment and say that some of the failures of the antipneumococcic serums in the treatment of lobar pneumonia are doubtless due to the hemolytic streptococcus. Therefore they advise that a specific antistreptococcus serum of a high titer be applied to both groups of pneumonias, believing that this will be the most effective agent in reducing the high mortality.

The results of the researches of Cumming, Spruit, and Lynch at Fort Sam Houston, were verified in essential particulars by the report of the commission sent by Surgeon-General Gorgas to Texas in February to study the pneumonia existing there.

This commission was composed of Drs. Rufus Cole, W. G. MacCallum and Oswald T. Avery, Contract Surgeons, United States Army, Captains A. R. Dochez and R. A. Kinselle, and Lieutenants F. G. Blake, T. M. Rivers, H. John, F. A. Stevens and William C. Von Glahn, Medical Reserve Corps. This especial study was undertaken at the Base Hospital, Fort Sam Houston, which was chosen for this work merely because pneumonia was prevailing there to a large extent at the time, and also because of its proximity to the laboratory of the Southern Department, where facilities were available for carrying out the bacteriological and pathological examinations. This report appears in the *Journal of the A. M. A.*, April 20, 1918, page 1146. It is entitled "Pneumonia at a Base Hospital." Part I deals with the etiology and clinical features of the pneumonia occurring in the hospital and was contributed by Dr. Cole. Part II deals with the pathology by W. G. MacCallum. The researches of the commission bring out many of the points concerning the bacteriology of the pneumonias occurring in the paper of Cumming, Spruit, and Lynch, already referred to. It was observed that pneumonia occurred frequently in the camp, but not always as a sequel of measles; that the coryza, conjunctivitis, and laryngitis produced by measles appeared to predispose to infection of the respiratory tract with bacteria; that streptococcus infection might occur in a person who had not had measles, and it is quite probable that other diseases, such as scarlet fever, predispose to it in the same way as measles. MacCallum says "When *Streptococcus hemolyticus* gained a foothold it usually caused in this series of cases the anatomic complex called here 'interstitial bronchopneumonia.' This is the same whether it is preceded by measles or scarlet fever, or by other diseases, and its characters are due to the specific effects of the streptococcus. When lobar pneumonia followed measles, the pneumococcus was in this series accompanied by the streptococcus, and in some cases the lobar pneumonia was complicated, anatomically, by the corresponding bronchopneumonia."

It was also observed that infection with the hemolytic streptococcus does not always cause an interstitial broncho pneumonia, but may produce a patchy lobular pneumonia.

The author states that "one of the most interesting features of our study of the cases in this hospital is the recognition of the invariable connection of *S. hemolyticus* with that characteristic anatomic lesion which was well known, but to which we have for convenience given the name 'interstitial bronchopneumonia.' * * * Empyema is a practically constant accompaniment of this condition and is of extremely serious import."

The report also states that "lobar" pneumonia due to pneumococcus has been found in many cases, not especially related to the occurrence of measles, but often complicated by secondary or coincident infection with *S. hemolyticus*.

One of the latest contributions to the bacteriology of the pneumonias is the report contributed by George F. Dick, M.D., of Chicago, and published in the *Journal of the A. M. A.* for May 25, 1918. It is entitled "A Bacteriological Study of the Pneumonia Occurring at Camp Pike, Arkansas." The study is based on sixty cases of pneumonia admitted to the base hospital during February and March. The evidence obtained by examination of the sputum was further substantiated in a number of cases by bacteriological examinations of the blood during

life and of the lungs after death. This report confirmed the statements of the other investigators quoted in relation to the frequency of the streptococcus as an etiological factor in penumonia.

The pneumococcus cases form 48 per cent. of the 60 cases studied; of these 21 per cent. were Type I, 34 per cent. Type II, and 45 per cent. Type IV. Only one case of Type III was observed.

In 46 per cent. of the cases streptococci were the predominating organisms; of these 46 per cent. were non-hemolytic. In the cases coming to necropsy the pneumonia in which this type of organisms was found resembled the ordinary pneumococcus lobar pneumonia.

As stated by the author, his series of cases is interesting on account of the high percentage of streptococcus infection particularly due to the non-hemolytic organisms, which were also found associated with cases diagnosed as influenza and in the pus from appendicitis.

Vaccine Treatment of the Pneumonias.—You will doubtless remember that in 1912 Sir A. Wright undertook some investigations for the purpose of testing out the value of bacterial vaccines in the prophylaxis and treatment of pneumonia. These investigations were carried on in the South African gold and diamond mines. At this time the existence of definite groups of the pneumococcus, distinct and possessing specific immune reactions, had not been definitely proved, so it is not known what groups of the pneumococcus were included in the vaccines he used. However, as pointed out by the *Lancet*, April 13, 1918, the results of these investigations were valuable as the remarkable reduction in the mortality of pneumonia among the native mine-workers fully demonstrated.

Mr. F. S. Lister, bacteriologist of the South Africa Institute for Medical Research, who independently worked out the differentiation of pneumococci into several distinct groups by a means of immune reactions (Publication 2, South Africa Institute of Medical Research, 1913), found that the pneumonia prevalent among the workers in the diamond mines at Kimberley, South Africa, is due, mainly to three groups of pneumococci. (Publication 10, South Africa Institute for Medical Research, 1917.)

The *Journal of the A. M. A.* for April 20, 1918, page 1163, informs us that Lister found that "three subcutaneous inoculations with the triple vaccine of the three groups prevent the occurrence of pneumonia as caused by members of these groups, but not the pneumonia due to other groups of the pneumococcus." From seven to ten million of pneumococci were given at each injection, the cocci being first killed by a germicide and not by heat.

The fact that Lister has apparently succeeded in preventing pneumonia caused by the pneumococcic groups of which his triple vaccine was made, is certainly worthy of serious consideration. "The suggestion lies near at hand that prophylactic inoculation with the prevailing groups of pneumococci should be given a thorough trial where susceptible persons are aggregated under conditions that usually cause the outbreak of pneumonia."

Lister found that his own serum, following vaccination, contained agglutinins and opsonins, against the type of organism injected, eight months after the last inoculation.

Cumming, Spruit, and Lynch, to whose report I have already referred, consider it advisable to vaccinate measles patients found to be hemolytic streptococcus carriers, and also advise vaccination against the streptococcus irrespective of measles patients, because the hemolytic streptococcus is of such universal prevalence, they believe that such universal vaccination would protect against the infection and if this procedure is carried out the case rate, as well as the mortality of the pneumonias, both pneumococcus and streptococcus, would be reduced by a large percentage. They suggest the use of a triple vaccination for this purpose, consisting of the hemolytic streptococcus and pneumococcus Types I and II.

Dr. E. C. Rosenow, of the Mayo Foundation, Rochester, Minn., reported results in the treatment of 200 cases of pneumonia with a partially autolyzed pneumococcic vaccine. In his report published in the *Journal of the A. M. A.*, March 16, 1918, he recommends that a polyvalent vaccine prepared in this manner be injected in all cases of lobar pneumonia as soon as the diagnosis can be made.

Mixed vaccines were opposed for a time by some of the specialists in vaccine therapy, also the use of stock vaccines, but more recent investigations have removed much of the prejudice. Dr. Aldo Castellani, Regius Professor of Tropical Medicine, University of Naples, and for some time in the British colonial service in Ceylon, as director of the Clinic for Tropical Diseases and Bacteriological Institute, was one of the first to emphasize the importance of mixed stock vaccines. For a number of years he advocated the mixed vaccine of typhoid and paratyphoid A and B. Not only did he advise the use of mixtures of typhoid and paratyphoid, but also suggested the addition of the microbes causing cholera, plague, and Malta fever. He furnished data to show that agglutinins developed in the serum as a result of the inoculation of such mixed vaccines were not less than when the vaccines were given separately. ("Some Recent Vaccine Therapy," by Alex. Fleming, F.R.C.S., *Practitioner*, April, 1917, page 322.)

In a private communication, dated Sklopje, Serbia, August 23, 1915, Dr. Thos. W. Jackson, a member of the commission appointed for the extermination of typhus fever in Serbia, referred to Castellani's "tetravaccine" (cholera, typhoid, and the paratyphoids) and said that it had been adopted by Dr. Richard P. Strong of the commission and also by the Serbian government. Dr. Jackson stated that more than 120,000 doses of this vaccine had already been administered without harmful results.

McCoy, in a paper appearing in the *Journal of the A. M. A.*, speaks in favor of mixed vaccines in typhoid fever. He says combined vaccines consisting of the typhoid bacillus, the two paratyphoids, the dysentery bacillus, and sometimes the cholera vibrio have been used to some extent. "There appears to be justification for the use of such combinations as preventives under special conditions."

Sir Almroth E. Wright has strongly advocated and applied a mixed "asepsis vaccine" prepared from mixed cultures for vaccination against mixed infections occurring in the wounded. According to the latest information at hand, half a million doses have been administered.

By means of the Abderhalden test, Smith demon-

strated in the Mulford Laboratories that specific antibodies for each of a number of varieties of bacteria are formed as a result of the inoculation of a mixture of the microorganisms employed, namely: *Staphylococcus aureus, Staphylococcus albus,* streptococcus, pneumococcus, *Bacillus influenzæ* and *Micrococcus catarrhalis.*

Now mixed typhoid and paratyphoid vaccination is almost exclusively practised in the army, and mixed vaccines for immunization against various mixed infections and for their treatment are quite in vogue. So it did not come to us with as much of a surprise when the above reports recommending mixed vaccines for immunization against pneumonia appeared. Nor were we surprised when one of our members, Dr. S. Solis-Cohen of Philadelphia, in a paper read before the Philadelphia County Medical Society, March 13, 1918, said that at Fort Oglethorpe, he had become conversant with the work of Capt. Arthur Dare and Dr. D. H. Bergey, assistant chief of the laboratory, who had put into execution at the hospital the treatment of pneumonias with a mixed vaccine and in more than a hundred cases of lobar pneumonia treated with this vaccine the death rate had been less than 6 per cent. (See Report Symposium on Pneumonia, MEDICAL RECORD, April 27, 1918, page 743.)

In the light of the above evidence and more of the same kind that might be presented if the time limits of this paper would permit, what advice shall be given the country doctor relative to pneumonia treatment without bacteriological diagnosis? In response to this question I have received the following answers:

1. Use antipneumococcic and antistreptococcic serum conjointly, employing the polyvalent serums. assuming that the patient is probably suffering with a mixed infection.

2. Use a polyvalent vaccine made from as many strains or types of the pneumococcus and streptococcus as it is possible to obtain. Preferably employ a sensitized vaccine, because the first step in the immunizing process has already been accomplished outside of the patient's body; therefore the immunizing response is more rapid and complete; moreover, there is less likelihood of severe reaction.

3. Use both serums and vaccines in the treatment of the same patient.

4. An original suggestion of my own: Have a serum prepared by immunizing horses against mixed cultures of pneumococcus and streptococcus. I presented this suggestion to one of the best known producers of biological products engaged in the preparation of serums and was informed that the preparation of such a serum was already under way.

11 WEST PHILELLENA STREET.

ACUTE INTESTINAL OBSTRUCTION.*

BY JEROME MORLEY LYNCH, M.D., F.A.C.S.,

AND

JOHN WILLIAM DRAPER, M.D., F.A.C.S.,

NEW YORK.

"ALL our notions, thoughts, sentiments, even the loftiest ideals, are drawn from experience; and no man can hope to trespass beyond the limits which God has been pleased to set to our experience.'"

We present herewith an analysis of our last twenty-four cases of acute intestinal obstruction occurring in twenty-two patients, showing a mortality of 25 per cent. We attribute this low mortality to several factors, the most important being early recognition, immediate operation and reliance on Murphy's famous dictum: "Get in quickly and get out quicker."

As to cause—5 were due to intusseption, 1 death; 5 to cancer, 2 deaths; 8 to postoperative bands or displacements, 3 deaths; 1 to hydronephrosis, and 3 to ileosphincteric transplanatation.

As to recurrence this occurred three times in one luetic individual several weeks apart, the last one being fatal.

Operative trauma. We are unable to connect mechanical traumata with postoperative obstruction, still holding, as we have said before, that adhesion formation is in direct proportion to the fibrogenetic and fibrolytic functions of the individual.

As to arbitrary periods in obstruction, we recognize three, the first until the 48th hour, the second until the 72d hour, the third after that hour.

As to time of operation, all patients operated upon during the first period lived; 90 per cent. in the second period lived; the mortality occurred in the third period, when, owing in large part to impairment of the detoxicating power of the liver most of the patients were beyond help.[2]

Drugs. The effect of these was most undesirable. Several cases were lost because of the mistaken idea that drugs were helping.

We now know that so-called adynamic ileus never kills a patient if the stomach and colon are washed out. It is simply nature's effort to cure by rest the localized peritonitis which always follows every operation, and, like every protective symptom should be let alone.

It is interesting to note how nearly the observations we have made on animals coincide with our findings in human cases, the most important of course being that the nearer the obstruction lies to the lethal line of the duodenum the more violent the symptoms and the graver the prognosis.[3]

The coefficient of relative toxicity in animals finds its counterpart in human beings. This is atural when we remember that the very spring of life is situated in that duodenal area where the important secretions of the pancreas and liver empty. This reminds one of the questions put to his class by a well-known professor of anatomy, "Why do the ducts of the pancreas and liver empty into the duodenum?"—the answer, of course, being that "these great glands arise from this portion of the gut." Since this is so, it follows that the epithelial hormones of these parts must be sympathetic, and that interference with one must cause a cataclysm in the others.

We have held for years to the endocrine rather than to the bacterial theory of acute obstructive death, and the recent human study herewith presented strengthens this belief. The bacterial co-

*In part from the Laboratory of Surgical Research, New York University

efficient which may play an important part in the chronic obstruction of the aboral portion of the gut has no place in the discussion of acute obstruction because it does not exist.

As to pain. Deaver, after reading a paper on intestinal obstruction, hurled back this answer to a member of the audience who asked his grounds for operating—"I operate for pain." In agreeing to this we qualify it as follows: "The intensity of the pain is directly proportionate to the strength and irregularity of the peristaltic wave." (Lynch.) The pain is periodic; increasing to a climax of intensity, followed by gradual decline to a period of rest. It is possible to chart this pain and the curve of its intensity will be found to agree very closely with the known curve of intestinal peristalsis. This is the period in which operation to be of use must be performed. During this period, which is usually up to the forty-eighth hour, there is no appreciable disturbance of pulse or temperature and no distention. The pain of peritonitis, on the contrary, presents a wholly different curve in that it is constant, never reaches zero, and is subject to very irregular fluctuations. One resembles a temperature chart of intermittent fever, the other of remittent fever.

The second period, starting often at the forty-eighth hour, is marked by vomiting, slight pulse rise, and may be by some distention.

The third period, after the seventy-second hour is characterized by marked changes. The character of the pain is changed, and its intensity is diminished but it remains more or less constant. This is due to peristaltic inaction due to localized peritonitis. It is a purely secondary and terminal condition influencing the pain, but not the outcome; since, as we have already shown, by this time the glucuronic pairing capacity of the liver is already fatally impaired and operative removal of the obstruction is useless. At this period also the patient becomes distended and apathetic and often feels better. This is a very serious danger signal, analagous to that often seen in gangrenous appendicitis. The vomiting is copious and, because protective, is proportionate to the requirements of the organism.

No patient has ever been saved from obstruction by any measure save operation. Countless lives have been lost by giving drugs. These only camouflage the fateful picture of intestinal obstruction; lull the physician into fancied security, and the patient into the grave. Why is this so? Because of the prevailing idea that there are two forms of intestinal obstruction, one medical, the other surgical. This is not true and the sooner it is recognized the better. One is lethal, the other protective; one is pathological, the other physiological. The point is to distinguish between the two. The one is a rapidly fatal intoxication arising from mechanical interference with the endocrine system, and is surgical; the other is the normal reaction of the organism to infection or to trauma, is protective and should therefore be encouraged. Whatever physiological obstruction symptoms result from it are easily cured by washing out the stomach. It is the old cart-before-the-horse story of giving medicine to lower blood pressure, to stop coughs, to check diarrhea without consideration of cause and effect. Esoteric protective symptoms are important.

Drugs are not the only danger. Enemas, while safe in themselves, often lend false and fancied security—so many men are encouraged by the passage of a little gas and feces, as to abandon operation, thereby putting the patient's life in jeopardy. The colon can be depended upon to produce considerable gas and feces at any time, and at almost any level, therefore, unless there is a distinct recession of all pain, with copious movements of both gas and feces, it is imperative to remember that the patient is still in danger.

Following abdominal operations it is, therefore, most unwise to harass the bowel with any form of medication, because, unless there is mechanical obstruction with its above-described pain symptom, the bowel may be depended upon to move spontaneously between the third and fifth days. Delay is protective and should never be interfered with.

Differential Diagnosis. We have on many previous occasions pointed out the similarity between the stomach and colon and we wish to emphasize that they therefore require similar treatment, viz., lavage.[3]

The distention of the third period of intestinal obstruction should be carefully differentiated from that due to acute distention of the stomach accompanying physiological obstruction and always easily relieved by lavage. We have recently seen three days postoperative to cholescystectomy, and nine days postoperative to developmental reconstruction, the abdomen so distended as to feel as tight as a drum; board like and tympanitic, the stomach occupying the entire abdominal cavity, as was proved when both patients were immediately relieved by lavage.

The crisis of tabes may often closely simulate intestinal obstruction and other abdominal conditions, but the history and examination of the spinal fluid will clear up the diagnosis. It is more difficult to differentiate between acute mesenteric vascular occlusion and acute obstruction. The early recognition of the former lesion is even more important than the latter because immediate operation and that alone will save the patient. The very severe pain with early distention, tenderness, movable dullness, fall of temperature, rapid pulse, persistent vomiting followed by constipation, occasionally a palpable tremor and always grave constitutional symptoms, these are the characteristics of obstruction in the mesenteric vessels.[5]

In acute fulminating pancreatitis the shock is severe from the start; the pain is excruciating, but is confined more to the upper abdominal region.[6]

Conclusions.—1. Pain is the cardinal symptom of acute intestinal obstruction. It is typical. It is characterized by exacerbations and remissions as well as by a rhythm similar to that of the peristaltic wave which causes it. "The intensity of the pain is directly proportionate to the strength and irregularity of the peristaltic wave." (Lynch.)

2. Clinically we recognize three periods in acute obstruction. These merge imperceptibly—

the first, until the forty-eighth hour; the second until the seventy-second hour; the third, after this hour. Operation within the first period is practically free from mortality. In the second it is high. In the third period it is a forlorn hope.

3. Drugs, especially cathartics, must be avoided. Enemas are useful, but the correct interpretation of their results is all important.

4. Acute intestinal obstruction of the oral bowel unless released early results in an endocrine death. Bacteria have nothing to do with it.

5. There is only one form of acute intestinal obstruction, viz., that caused by mechanical means. The so-called adynamic or paralytic form should be looked upon in its true light, viz., that of a protective symptom and valued accordingly.

VARIABLE HYPEROPIC ASTIGMATISM IN CHILDREN AND ITS CORRECTION.

By EVERETT S. McCLELLAND, A.M., M.D.,

LOS ANGELES, CALIFORNIA.

To write approvingly upon some popular theme universally accredited as true is, indeed, a pleasant and easy task, but when we turn to dispute a long-established principle, then prejudice is apt to obscure judgment. Because many refuse to question established teachings must we fail in our just estimation of evidence, even though it tends to disprove age-long beliefs?

Astigmatism seems to be considered an invariable defect or one which changes but slowly during periods of months or years. The lack of a symmetrical corneal curvature does give rise to a more or less permanent defect called corneal astigmatism. This defect constitutes the major amount of all astigmatism. Again an inequality of the refracting power of the lens may manifest itself in an astigmatic defect which is slightly if at all variable. The latter, or lenticular astigmatism is usually of a minor character and much less frequent than corneal astigmatism. Still less frequent of the permanent type are those caused by ptyrigia or scars. Permanent forms of astigmatism may be either myopic or hyperopic and found in subjects of any age.

The purpose of this article is to summarize the clinical evidence furnished by the refraction of about 200 cases of astigmatism, out of a series of about 750 cases, between the age of six and twelve, who came under the author's attention at the Los Angeles Public School Dispensary and in his private practice, demonstrating that there also exists a variable form of astigmatism in children, which cannot be corrected by the popular methods of using the chart at 20 feet, with or without a paralyzed accommodation, or by using the retinoscope while the accommodation is thus suspended, and that a single pair of lenses will not correct this astigmatic defect in children of this age for all distances within one-quarter of a diopter in about 20 per cent. of all cases, and that therefore the lenses should be prescribed which correct their near or working distance.

Variable astigmatism is possibly caused by the inability of the eye to maintain a perfect ratio of refraction while passing through its range of accommodation. It is an error which is not easily corrected and its correction is, as a rule, notoriously neglected. This form of astigmatism is found only in children who have, at least, a normal range of accommodation and is always of the hyperopic variety, never myopic.

Variable astigmatism is correlated with accommodation. The greater the range of accommodation, the greater the possible variation. The less the range of accommodation in the subject the less the possible variation. It is most evident in the child and least evident in the presbyope—gradually decreasing from childhood to old age.

By variable astigmatism we do not refer to that temporary variable type so familiar to every refractionist, which is caused by an irregular spasmodic contraction of an irritated ciliary muscle, so common in the hyperopic patient under thirty years of age and which compels the patient, if his accommodation has not been paralyzed, to pronounce one and then the other of the astigmatic letters as the brightest to the confusion of the refractionist. This is only temporarily an abnormal condition whose chief importance is that it be neglected.

By variable astigmatism we mean that form which compels the patient invariably to pronounce a certain astigmatic letter as the brightest when seated at a definite measured distance from the chart, but to pronounce a different letter as the brightest when this distance is changed; that form which compels the patient to pronounce some particular letter as the brightest after a definite amount of sphere has been added or subtracted from his accommodation; that form which causes the child continually and invariably to pronounce certain letters in definite order as the brightest while approaching the chart and to enumerate these letters in the reverse order as it recedes from the chart; that form which may cause even the adult who has been accurately corrected for the ordinary 20 feet to observe that one and then the other of the astigmatic letters become the brighter as he approaches the chart from 20 to 10 feet; that form which is "brought out" so as to be measured by the chart only at some definite degree of the patient's accommodation.

This variable form of astigmatism maintains a definite kind and amount for each degree of accommodation. A correction of variable astigmatism for the standard 20 feet when it is associated with the constant form or when it exists alone, may not only fail to furnish a correction for the near or working distance but may, and often does, increase the defect. Optical defects should be corrected for the eye at work and not for

the eye when relaxed, as for 20 feet or infinity.

The reader having followed to this point, may reasonably ask how is it possible for a form of astigmatism to exist so commonly in the eyes of children which varies with their accommodation and requires a definite correction for a definite distance? The following possibilities may be suggested:

1. The axis of the cornea and the axis of the lens may not correspond throughout the various degrees of accommodation.

2. The ciliary muscle may not be capable of a uniform amount of contraction for each degree of accommodation.

3. The varying distances between the anterior surface of the lens and cornea along with a variation of the amount and density of the aqueous humor between these organs during the changes of an active accommodation, may have some influence.

4. The lens may not be capable of maintaining a uniform curvature of its refracting surfaces or a uniform density of all its segments as it passes through its accommodative range.

Any one or combination of these possibilities may account for the fact that a minor hyperopic astigmatism not at all evident at 20 feet, or one which has been accurately corrected for that distance, may become so modified by a change of accommodation that there is an uncorrected and disturbing error for the reading distance.

Assuming that these defects are possible, we still must marvel that the eye approaches so nearly a perfect automatic instrument especially in the child with its normal range of from 13.5 to 14 diopters of accommodation. Considered merely as a part of an optical instrument the lens of the eye of the vertebrate stands alone in efficiency. The artificial construction of such a mechanism, capable of an automatic transformation into an infinite number of lenses by which any point from infinity back to within 9 inches of itself could be focused upon a screen is incomprehensible.

Variable astigmatism is hyperopic, rarely, if ever, myopic. The author has known of but one case of marked myopic astigmatis in which the correction for 20 feet was not also the proper correction for the reading distance. He has no reason to offer for this exception. Variable astigmatism is hyperopic, as a rule, because it is developed by accommodation if one or more of the refracting elements of the eye are not in perfect coordination, as formerly suggested. But how shall we explain that the exact correction of hyperopic astigmatism for the working distance is so important? Only uncorrected hyperopic defects of any kind, as a rule, become the source of local and reflex irritation. Out of this series of cases from which these 200 cases under discussion were taken, 98 per cent. suffering with optical defects were hyperopic, but not over 0.1 per cent. of myopes uncorrected ever complained of any trouble which would be attributed to this defect alone, except a lack of vision.

When we consider the mechanism of accommodation we can understand how the eye can be under a strain only in its attempt to overcome hyperopia.

Accommodation is an active effort, consisting chiefly of a contraction of the circular ciliary muscle surrounding the circumference of the lens by which the convexity of the lens is increased and the focal distance back of the lens decreased. This process takes place in the normal eye when adjusted for any distance inside of 20 feet. In the normal eye the accommodation for any distance from infinity to within 13 inches of itself is made with comparative ease, but even then the eye finds relief in an occasional relaxation for infinity, because all muscular effort required in accommodating is then suspended. If the eye is hyperopic its effort for near work is always an abnormal one, because the ciliary muscle must contract beyond its physiological limit. The contractibility and strength of this tiny muscle must normally be very great, greater, perhaps, than that of any other similar amount of muscle tissue in the body. Probably no other muscle of the body could maintain a similar and continuous strain for 10 minutes as does this one hour after hour while the eye is focused for near work. On account of its relative strength many simple hyperopic defects in healthy children do not need correction until for some reason the general muscular tone of the child falls below normal, when this muscle is compelled to rebel against its excessive exertion. No refractive defect of the eye can be corrected or even partially corrected by the eye itself, except by an abnormal contraction of this muscle so that myopic defects cannot in themselves produce local or reflex irritation. The myopic eye is not able to make any effort to correct its defect. It can make no active effort to see. Its accommodation is always suspended in proportion to its distant point within 20 feet. If the myoptic eye has a distant point as near as the ordinary reading point or distance it then has no accommodation. Unless the myopic eye is also associated with hyperopic astigmatism its ciliary muscle can never be called upon to make an abnormal contraction. The myope who complains of eyestrain usually has hyperopic astigmatism or has been over corrected with a minus lens and made artificially hyperopic, or has abused his eyes by excessive use as we often find among Japanese students, or has large pupils and a light-colored iris, admitting an excessive amount of light through indirect vision.

An overcorrection of myopic astigmatism is as apt to cause trouble, as a failure to correct hyperopic astigmatism fully, because in the former the patient is made artificially hyperopic and we have an unusual and unnecessary demand made upon accommodation—something in which the myopic eye is already deficient.

The author has become convinced after his experience in this series of cases that there are three things of utmost importance in making satisfactory corrections for hyperopic astigmatism in children which do not seem to be sufficiently emphasized if at all mentioned in text books and treatises on the subject; viz.: (1) The prescribing of the exact axis and its proper maintenance. (2) The prescribing of the pupillary distance of this axis to suit the working distance of the patient. (3) The full correction of the hyperopic

astigmatism for the working distance of the patient.

1. There is no excuse for not determining the axis within a few degrees at least. A very satisfactory and quick method for checking up the direction of the axis following the use of the retinoscope is to insert into the trial frame a cylinder of about one diopter more than that found to correct the defect by the dynamic method and then turn the axis of the cylinder until the child says it can see best. This will seldom fail to add valuable evidence as to the exact direction of the axis provided that the child is old enough to realize what is wanted. The inefficiency of a nose-piece alone, without temples, for the maintenance of the cylinder in its proper position is so generally recognized that it needs no comment.

2. Unless some muscular trouble requires a decentering of the lens the pupillary distance for school children should always be given for their near work. This pupillary distance will not disturb the eye when the accommodation is suspended for distance.

3. Our experience seemed to suggest that there was only one method of making the exact correction for hyperopic astigmatism in young children and that was by the dynamic method of retinoscopy.

An attempt to correct astigmatism in school children by the chart was found impractical. If the accommodation was fully paralyzed with a mydriatic, the chart correction was for infinity and not for the working distance. If a mydriatic was not used the chart was impractical, because even if the child was able to interpret what it saw its ciliary muscles were usually so sensitive that the appearance of the astigmatic letters constantly changed in their distinctness; however, if a correction could be made by this method it would be for a relaxed eye only.

In an adult or one nearing the presbyopic age the conditions are quite different. The ciliary body is not so irritable, but that by using the chart and the foregoing method a practical correction can be made, even without the danger of a mydriatic. The adult does not often require an exact correction for his astigmatism, not only because the ciliary body is less subject to irritation, but because variable astigmatism is absent at least in proportion to his decreased power of accommodation. In fact, many presbyopes who have never worn a full correction for their astigmatism do not always seem pleased with it, especially if they possess one with an off axis.

The static method of retinoscopy with its fully paralyzed accommodation was not found satisfactory for the correction of astigmatism in children of this age, although indispensable for differential diagnoses because irregularities of the cornea and lens increase from their visual axis outward toward their circumferences.

These irregularities are suggested by the visual acuity one obtains by looking through a pinhole disk in startling contrast to the blurred vision one must experience through a fully dilated pupil. The retinoscopic evidences of these irregularities become a source of great confusion in attempting to use the static method. Various scissor-like movements, exaggerated shadows (indicating a much greater amount of astigmatism than was actually present) kaleidoscopic movements from mixed peripheral astigmatism, each associated with chromatic aberration often entirely disappeared after the pupil had returned to its normal size and accommodation had again asserted itself. As it is unnecessary to correct optical defects outside of the normal pupillary area these peripheral shadows developed by the static method when the pupil is fully dilated are a source of unnecessary confusion in attempting to make the important pupillary correction. Even if it were possible to make the proper pupillary correction under such disadvantages we still would have failed to have made the correction for the working distance. Our correction would be for infinity and a suspended accommodation. Optical defects do not cause reflex irritation while the accommodation is suspended, but while it is active as previously illustrated when referring to myopia.

The dynamic method of retinoscopy proved the most satisfactory in making corrections of this kind and for children of this age. By this method we only attempt to correct or neutralize the shadows which represent defect over the pupillary area—defects which are concerned with actual vision—and at the same time we are making our corrections for an active accommodation and for the child's working distance. The only secret in the technique of this method is in the use of not less than an eighty-candlepower lamp in a dark room and some interesting design on the oculist's forehead, at a meter's distance, to attract the attention of the child. The lamp should emit its light as nearly from a point as possible through a diaphragm with an opening of about 1 cm. in diameter. With such a light the author likes to use a small, flat, unperforated retinoscope, but details may suit the choice of the physician. An arrangement as illustrated in the diagram has proven very satisfactory with the author for rapid dynamic work. A strong light, the retinoscope, and the eye to be corrected focused for a meter's distance are the all-important conditions for the correction of variable astigmatism.

Summary.—1. There is a form of hyperopic astigmatism in children which varies with accommodation, and the greater the power of accommodation the greater the possibility of this variation.

2. A correction of hyperopic astigmatism in children for the standard twenty feet often fails to correct this or a similar error for the working distance.

3. A child's eyes when relaxed may show no astigmatism, but when accommodated for the working distance may possess a disturbing astigmatic error which is usually hyperopic.

4. It is necessary to give the hyperopic child a full correction for his near work because the hyperopic eye suffers from its refractive errors while at work and not while relaxed for distance.

5. Variable astigmatism is not associated with myopia because it is dependent upon a long range of accommodation and the myopic eye has less than a normal amount of accommodatiton. A correction of myopic astigmatism for twenty feet is

therefore sufficient for the near or working distance.

6. As the myopic eye can scarcely suffer from an accommodation strain the full correction of myopic astigmatism is desirable, only to increase acuteness of vision.

7. An overcorrection of myopic astigmatism is as apt to cause trouble as a failure to correct hyperopic astigmatism fully, because in the former case the eye is made artificially hyperopic and an excessive demand is made upon accommodation, something in which the myopic eye is particularly deficient.

8. The pupillary distance for the astigmatic child should be measured for its working distance. A decentered lens is not so apt to cause trouble for a relaxed eye as for an accommodated one.

9. The dynamic method of retinoscopy is the only satisfactory one for the correction of hyperopic astigmatism in the child, because it eliminates the confusing and unimportant shadows of exaggerated astigmatism and other peripheral defects exposed by a fully dilated pupil and also because it corrects an accommodated eye and not a relaxed one. Details, like tools for other work, may suit the individuality of the physician, but two things are of utmost importance in the correction of variable or hyperopic astigmatism in children, viz., a concentrated light of not less than eighty candle power properly arranged and the eye to be corrected focused for a meter's distance.

RABELAIS' MENTION OF PARTS OF THE HUMAN SKELETON.

By Douglass W. Montgomery, M.D.,

San Francisco, Calif.

Rabelais mentions specifically parts of the human skeleton thirty-two times in the five books; eighteen times in the first book, twice in the second book, twice in the third book, seven times in the fourth book, and three times in the fifth book. It is interesting that this should occur so frequently in a popular satire, and it was probably partly due to Rabelais being a physician particularly interested in anatomy, and also to the highly objective way he had of describing the human being; and in addition there was the popular interest taken in anatomy and in bones at that time.

References to the skeleton in Gargantua.

31. Les os bregmatiques (the parietal bones), Pantagruel, Book V, Chapter XXVII.
32. Les mandibules, Pantagruel, Book V, Chapter XLVI.

The Jaws.—The jaws are mentioned eight times, and in seven of these instances they are called mandibules, and in only one, machoire, the usual modern French appelation. In one instance Rabelais speaks of twisting and wrenching the jaws from right to left as if he considered the upper jaw movable. In another situation he employs the term mandibule, the lower jaw, just as is now customary in English when it is used at all. One of the pilgrims whom Gargantua inadvertently had taken into his mouth on a salad leaf was walking around on the dental crowns, and his staff accidentally slipped into a hollow tooth, causing exquisite pain to the nerve of the jaw, which, of course, must have been the lower one, as the pilgrim could not walk along the upper teeth.

Coronal Suture.—It was a beautiful September day in Touraine, the native country of Rabelais, and the shepherds were guarding the grapes from the predatory birds. Just then the cake bakers of Lerné passed along the road with a full load of freshly baked cakes. The shepherds were seized with a desire to eat grapes with cakes, a most celestial food, and a delightful laxative for the bowels. Forgier, one of the shepherds, begged Marguet, the standard bearer of the cake bakers' union, to let him have some cakes for good money paid down on the nail. Marquet received the offer with derision, and on Forgier insisting, he pretended to accede to his request, and on his approach gave him a vicious cut with a whip, about the legs, and then rode

quickly away. The good Forgier, incensed beyond endurance, threw his stick at him. The stick, as if directed by fate, sailed through the air, probably point first, and lit on the fleeing Marquet's skull, exactly on the coronal suture and the chrotaphic, that is the temporal, artery. This was the cause and the beginning of the great Picrocholian war.

Marquet was grievously wounded, as was natural, for the stick, as before mentioned, probably hit end on, and therefore with its full weight behind it, and the force of the blow was received in a small area, the size of the end of the stick. Besides this the blow fell in the region of the temple, which has always been held to be particularly vulnerable. To expose the region to the assailant, Marquet must have been turning his head with a sardonic smile on his face, as enjoying the discomfiture of the injured Forgier.

Marquet, the standard bearer of the cake bakers' union, was undoubtedly a man of much importance, for his injuries were attended to by a number of surgeons, who afterwards were tendered large fees for their services. The welts on the humble Forgier's legs, however, were soothed by simple grape poultices, applied by his fellow grape pickers.

That such grave political consequences should follow the injury to a union man shows that the world has undergone no notable change in this regard in the intervening four centuries. The nomenclature of the coronal and of the sagittal sutures has also remained undisturbed.

Cranium.—In the great Pichrocolian war it fell out that Friar John was taken prisoner by a troop of marauders, who left him in charge of two archers, who were so intent on the progress of other events in the field of battle that they neglected to put the friar on parole, to disarm him, or to observe his movements. He seized the opportunity to cut one guard's throat and then attacked the other, slicing off the top of his head equatorially, just above the level of the petrous portion of the temporal bones, in such a manner as to cut away the parietal bones joined by their sagittal suture, together with a large portion of the frontal bone, and passing through the two meninges, opened up the two lateral ventricles. The top of the cranium was thrown back over the shoulders, still attached posteriorly to the head of the pericranium, and so resembled a doctor's cap, black below and red within.

Rabelais specially mentions that this terrific blow passed above the very solid petrous portion of the temporal bones—in other words, he was willing to tell a lie, but there were limits. In this, as he himself stated in this very book, he was not as bad as Pliny and a number of other writers on natural history.

Gargantua in this tale speaks of the os petreux as if it were a separate bone. It is now always called the petrous portion of the temporal bone.

The parietal bones are called the bregmatic bones, from the Greek bregma, the top of the head, and the frontal bone is called the coronal bone (l'os coronal).

In another situation Rabelais speaks of the Quavering Friars as having the posterior part of the head and neck, from the summit down to the scapulæ (omoplates) shaved, while the hair of the fore part of the head, as far back as the bregmatic bones, was allowed to grow freely.[4] It is an example of the many curious ways the religious orders then had of characteristically fashioning their hair.

Besides the petrous portion of the temporal bone, the acromion process of the scapula seems to have been regarded as a bone apart, as Rabelais mentions l'os acromion, the acromion bone.

The clavicle, the little key bone, was then called the jugulum or joining bone, as joining the arm to the body. This word also served to designate the hollow in the neck above the clavicle, and also the throat. Rabelais appears to be the originator of the epithet as applied to the veins of the neck (veines jugulaires). It was afterwards used in the same sense by Canappe (1541) and by Ambroise Paré (vaisseaux jugulaires),[2] and so has come down to our day.

The word faucile, sickle, was applied to the bones of the forearm and also to the bones of the leg. The faucilia minora were the radius and the fibula or peroneus, and the faucilia majora, the ulna or cubitus, and the tibia. The word faucile also was applied to the physicians' robe. It was so called because its sleeves were such a prominent feature; it had four, two of them reached to the hand and two hung down from the elbow.[3]

Ischium.—In the phrase "desgondait les ischies" Rabelais meant luxated the hips; that is to say, drove the head of the femur out of the cotyloid cavity. According to James, Hippocrates by "ischion" means the entire articulation of the thigh on the pelvis, or possibly the head of the femur.[4]

Ischie or ischia also meant sciatica,[5] and people unacquainted with anatomy still speak of this disease as a pain in the hip. Now, of course, the name is limited to the "sit down" bone.

It has been said that if you wish to know what people thought in the Middle Ages consult Rabelais, that incarnation of the Middle Ages turning to the light of the Renascence. Toward the end of the period, about the year 1500, people had become mightily interested in bones, and there were several very good reasons for this.

Anatomy itself was a new and progressive science, and a knowledge of it contributed to the reputation of a physician. Rabelais' renown as a physician no doubt rested to no inconsidèrable extent on his knowledge of anatomy, on which he at one time lectured. But probably the study of anatomy was then pursued more enthusiastically by artists than by physicians, as, for example, by Benvenuto Cellini, Michael Angelo and especially by Leonardo da Vinci. In addition to this many theologians were then striving to find in anatomy a substantial basis for the soul. It was an old belief, reaching back to the origin of the Hebrew Scriptures, that the blood was the seat of the soul, or aura or spiritual breath, and it was in investigating along this line that Michael Servetus studied the lungs and the pulmonary circulation, in order to know the exact constitution of the portal by which this "breath" would enter.

While theologians, artists and physicians were studying anatomy for their several spiritual, artistic, or scientific needs, collectors were busy, as never before or since, collecting the bones of the saints as relics. This peculiar collecting mania would nat-

urally encourage the study of osteology, for while the Church was decidedly opposed to dissection, her encouragement in the trade in relics, mostly bones, would facilitate their study by stimulating interest and by making them easily attainable. A bone collector of this particular stripe would add the enthusiasm of a collector to the fanaticism of religion, and as the human being is never quite so funny as when he is in deadly earnest, this contributed to the grotesqueness of the mania and gave an admirable opportunity for Rabelais, the great Mocker, to make sport of it.

Besides this, the enumeration of long lists of bones would be quite congenial to Rabelais, who liked long lists of things, and he would also like them because many anatomical structures had high sounding names derived from the Greek, such as "lambdoidal," which would especially appeal to a Greek scholar like Rabelais, who would be all the more inclined to employ them because Greek was especially hated by the reactionaries.

The occasion for employing "lambdoidal" was when Friar John, with his crucifix staff, chased the Picrocholian marauders out of the vineyard of the abbey. If any one of them wished to save himself by running away, Friar John broke his head in pieces by hitting him on the lambdoidal suture.[4]

The New Mania for Collections.—Toward the end of the fifteenth and the beginning of the sixteenth centuries collecting on a grand scale was a new thing. Rudolph II of Germany (1552-1612) is dean of all collectors. He did nothing else. He sat in his beautiful castle, the Rhadchin, in Prague, and collected curiosities and works of art of all kinds, and would receive no one in regard to any business of the empire over which he ruled. Ambassadors from foreign lands and emissaries from his own dominions would wait years for an audience, and to such requests he would return the answer, "Er sei eben mit andern Geschäften trefflich molestiret," "His majesty is just now excellently well occupied with other affairs." His mania and his inefficiency cost him his imperial throne and, like all inefficient people, he was embittered and petulant at receiving his just deserts.

Rudolph's uncle, Philip II of Spain, was more of a specialist, and became the greatest collector of saints' bones that ever lived. John Hay says of him that, with the possible exception of Cuvier, he could see more in a bone than any man that ever lived. In his long life of osseous enthusiasm he collected 7,421 relics—whole skeletons, odd shins, teeth, toenails, and skulls of martyrs—sometimes by a miracle of special grace getting duplicate skeletons of the same saint.[8] Philip believed that these venerable pieces of phosphate were endowed with a sort of radiant energy, resulting in miracles.

Furthermore, it was believed that man was made of clay and therefore the human body could be regarded as a sort of animated pottery, of which the bones, as more nearly resembling pottery in appearance, might therefore be esteemed the most fundamental parts. It must also be taken into account that the gloomy Philip and the host of bone collectors, of whom he was only the chief, represented a morbid type of mind very common in the Middle Ages, where people experienced a sort of ecstasy in the contemplation of death. How differently constituted was Philip's august physician, the learned and original anatomist, Vesalius, who said that "one could get more out of one experiment on the human body than from years of dissection." The one had his face turned toward light and life, the other toward death and stagnation. There is no doubt that Vesalius was very unhappy in Philip's somber, wearisome court, and that Philip's dry bones were imperfectly satisfying to his hungry spirit.

There is reason to believe that Philip and those likeminded with him had come to view the whole hierarchy of heaven, together with the saints on earth, as a sort of relic mine. There was even an imprecation "by God's head full of relics." The Escorial, Philip's pet building, was erected as a sort of safe-deposit box for the royal bones of his line.

Besides this anatomical tendency of the times, inducing a popular writer to include in his works long anatomical lists, one must not forget that Rabelais was a physician and an anatomist. Most of the scenes in which these anatomical lists occur are a sort of "rough house" or "horseplay" such as would be indulged in by students, and they may have been taken out of Rabelais' own notebook, dotted down while he was a student in Montpelier.

THE HOMIGRADE THERMOMETER.*

By F. E. ASPINWALL, M.D.,

La Grange, Ky.

The Homigrade system of temperature measurement is based on human nature. Its foundation is, therefore, secure. It recognizes the natural tendency of man to make his own normal within the radius of common sensation the criterion or measure of temperature values, and it reduces this natural system of temperature measurement to scientific accuracy. Because of the decimal feature of this scale its figures are not only very expressive, but their values are instantly and vividly apparent. In this respect this scale is totally different from all others, the values of their figures being obscure and the figures themselves very often misleading.

The two fixed points of this scale are freezing and boiling, just as in other systems, with 0 at the former and 270 at the latter point, the peculiar features and advantages of the system depending on the consequent figures at other important points.

What may be called the four cardinal points of the homigrade thermometer are 100° H., 50° H.,

*Homigrade: Human Scale.

0° H., and —50° H., each defined briefly below:

100° H. (98.6° F.) "Blood heat," or the full human normal at and near the surface of the body within the radius of common sensation. To all human kind this is the best known temperature and the natural criterion or measure of temperature values. This surface temperature is subject to many variations, due to both internal and external influences, but this figure expresses the full normal, above which is fever, and all departures from this normal are felt as more or less discomfort. This point also marks the upper limit of normal summer heat, above this point the heat being extreme and proportionally oppressive.

50° H. (65.3° F.) is the halfway point between freezing and the human normal; also the lower margin of summer heat and the upper limit of spring and autumn heat. It is a satisfaction to know the exact point at which the rising temperature passes from spring to summer heat, this not being apparent in any other scale.

0° H. (32° F.). The freezing point. This point is also the vital heat zero, for in any organism it marks the complete cessation of vital action therein. It is also the lower border of spring and autumn heat, and the upper limit or least degree of winter cold. Above this point only, therefore, are the values positive, actual vital heat assets.

—50° H. (—1.3° F.) is the lower limit of normal winter cold (exhaustion of heat). All freezing (winter) temperatures are minus values, for in all organisms they are incompatible with vital functioning. Hence vital heat should be measured from the freezing point and should not include in the measure any freezing temperatures.

The above account of the four cardinal points shows an ideal division of the seasonal temperatures with remarkably fitting figures, there being a normal range for each season of exactly 50 Homigrade degrees. It also shows that the human normal is exactly 100 Homigrade degrees above the vital heat zero. Hence each degree in this system equals 1 per cent. of this normal. The degrees below freezing, though of equal measure, as explained above, are minus values corresponding to the debts or liabilities of a person or corporation, and the figures expressing them are preceded by the minus sign. Every temperature, therefore, is expressed relatively to both the vital heat zero and the human normal, a definitely understood measure from the former and a true percentage of the latter, thus imparting an otherwise impossible sense of temperature values.

This wonderful double meaning scale adds a heretofore unknown interest to all temperature studies. It opens new views to nature students and discloses many facts not otherwise apparent. Its shorter degrees necessitate a less frequent use of fractions and with or without fractions afford greater precision.

Food Desiccation in Germany.—While the normal desiccating industries—milk for example—were injured by the war, the drying of certain food products shows an enormous increase. Comprised here are cereals, fodder of all kinds, potatoes and beet tops. If surplus potatoes are at once dried, the effects of freezing and putrefaction are forestalled.—*La Presse Médicale.*

Medicolegal Notes.

Construction of Harrison Anti-Narcotic Law—Primarily a Revenue Measure.—An indictment in the words of section 2 of the Harrison Anti-Narcotic Act alleged that the defendant, a Texas physician, who had duly registered and paid the special tax of one dollar required by the act, did unlawfully and knowingly sell and give away a quantity of heroin tablets, which sale was not made in pursuance of a written order on a form issued in blank by the commissioner of internal revenue. A second count of the indictment was identical with the first, except that it charged that the defendant did unlawfully, knowingly, and willfully sell, dispense and distribute heroin tablets not in the regular course of his professional practice, and not in the treatment of any disease, but to one then addicted to the drug habit. The two counts in the indictment, the federal district court for the Western District of Texas holds, do not state offenses against the laws of the United States. The acts charged to have been omitted and committed are violations of police regulations incidental to the taxing purpose of the act, and which do not tend to render effectual its prime object, revenue. To that extent the statute is in violation of article 10 of the Constitution of the United States. The main purpose of the act is to provide for a tax and enforce its collection for the legitimate sale or disposal of opium and its derivatives. Consequently any regulation of law or provision that aids in the enforcement of the collection of this tax is within the rights of Congress. In re Kollock, 165 U. S. 526.

The two counts of the indictment show that the defendant was a physician who had duly registered and paid the special tax. It is not made to appear in what particular the requirement that a written order must be given by the purchaser to the seller renders effective the enforcement or collection of the tax, especially in this instance, where the tax is shown to have been paid by a person duly registered. It is clear, looking to the provision of the statute as to this requirement, that it has an important bearing, as a police measure, in safeguarding the dispensing and distribution of the drug so that it may be limited in its use to persons actually in need of it as a medicine. A consideration of the whole act, and of the many regulations of the Treasury Department governing the sale and control of the drug, leads to the conclusion that greater efforts are made in the measure to protect against misuse of the drug than to its enforcement as a revenue act. This reasoning was held to apply more forcibly to the second count. There the regulations requiring the drug to be dispensed by a physician only in the course of professional practice, after having duly registered and paid the tax, can only be a police measure looking primarily to the protection of the public against the abuse of this drug, not remotely serving as an aid or means to effect the object of the act in respect of its revenue. —United States v. Doremus, 246 Fed. 958.

Malpractice—Jury Cases—Expert's Opinions.—In actions by a wife and her husband against a physician for negligence in his treatment and care of the wife after she had given birth to a child in that, while suffering from convulsions, the defendant negligently directed that she be held in bed by holding her by the wrists, whereby her shoulders became dislocated and fractured, and in that later the defendant failed to discover such injury, and negligently prescribed treatment which caused her great pain and resulted in permanent disabilities, the defendant's liability was held for the jury. An important question was whether the fracture and dislocation were due to the wife's convulsions alone or resulted from the convulsions together with the restraint exercised upon her by the defendant physician. It was held that the testimony of a medical expert as to whether, from his examination of a plate and the plaintiff, and the evidence in the case, he had formed any opinion as to the cause of the present condition of the plaintiff's left shoulder was inadmissible, since an expert witness cannot express an opinion founded in whole or in part on conflicting evidence. Defendant's exceptions to verdicts for the plaintiffs were sustained.—Connor v. O'Donnell, Massachusetts Supreme Judicial Court, 119 N. E. 446.

Military Medicine.

Appendicitis from Gassing.—That war gases produce digestive disturbances when swallowed has been known from the outset; the relative prominence of digestive symptoms has been believed to be due to the amount of gas which was swallowed. With the increase of our knowledge, it has become apparent that erosions due to the direct action of the gas might form the starting point of ulcers. The principal lesion is, of course, transitory gastritis or gastroenteritis. It has been known that the colon even can participate to a moderate degree in the reaction. Recently Moutier has published an article, an abstract of which appears in the *Journal de médecine et de chirurgie pratiques* for July 10, on an appendicular reaction set up by swallowed gas, with especial reference to the contained chlorine. He reports eight cases, but the number actually seen by him is much larger. As a matter of fact the coincidence is by no means rare. A distinction must at once be made between the patient with a history pointing to appendicitis and one without such history. The two groups appear to be of about the same incidence so far as the author's material reaches, although the superacute cases are somewhat more numerous. An incubation period, uually indeterminate in appendicitis as a whole, is naturally in evidence here, and is from 5 to 8 days after gassing. In the cases suggesting a relapse of an old trouble the incubation appeared to be longer than in the very acute cases and two weeks elapsed in several of this type. In no case was the onset of the attack fulminating. The evolution of the disease was rapid, however, and progressive. The presence of the subacute gastritis naturally masks the appendix symptoms to some extent, but even with this handicap these manifestations were not severe. There was always nausea, but vomiting was absent. The general reaction was decidedly mild, there being but little elevation of temperature. There was tenderness with rigidity on pressure over the appendix. The course of the disease was decidedly brief and mild. Its importance does not seem to be great and the chief element of interest lies in its suggestiveness, for it is obvious that merely irritating ingesta may be sufficient to cause appendicitis of a mild type. Other hypotheses are not excluded —for example, secondary infection and the sequence seen at times after burns.

Trench Lung.—This term has been applied to certain pulmonary symptoms unaccompanied by organic disease which occur during prolonged trench life. Naturally they have been placed by some writers under neuropathic phenomena. The subject has recently been made the theme of a graduation thesis by Saint-Aude. The symptoms are by no means rare, and comprise a tachypnea, such as might conceivably be due to excitement because most noticeable under trying conditions, as after shell explosions and before assaults. This banal symptom which might occur to nearly every combatant, is not of course to be dignified by the name of trench lung. The tachypnea referred to is somewhat more than this simple phenomenon and is a persistent acceleration of respiration—one in evidence after the exciting causes have quite subsided. Moreover, the determining factor is not a transitory emotional experience but rather a sustained emotional stress such as a prolonged bombardment. The tachypnea being purely psychogenic can be made to subside rapidly at times by purely suggestive measures. If this were all there is to trench lung the condition would not merit the name, but after the subject has been removed far from the battle zone and is tranquilly situated, the symptom recurs without apparent motivation. It appears by paroxysms and the picture at once becomes striking, for the crises of rapid breathing accompanied by agitation are absolutely unattended by a single organic manifestation. The subject in his distress may rush back and forth in his room, groaning and crying for aid; his inspiration and expiration may alike be noisy. The thorax is seen to make normal excursions and the pulse remains good. To this condition is added a hyperpnea of effort, for the slightest physical activity may be seen to increase the respiration. As a consequence of this tendency the subject, when not agitated, is found relaxed on his back, in which position he refrains from the slightest voluntary effort. It is from this passive state that he is aroused by the spontaneous crises of the disease. It is evident that in the intervals between crises he is still menaced by effort dyspnea. The best preventive of the crises is isolation and the best treatment of the paroxysm is flagellation of the thorax with a cold towel. A radical cure by psychotherapy is believed to be practicable.

Psychology of Mental Confusion.—Duprat of the experimental psychological station at Aix-en-Province considers this subject in *Le Progrès Médical* for April 13. The term as applied to soldiers has been somewhat abused, because under such designation psychic torpor, mere retardation to queries, memory lapses, etc., were included. In such conditions it is easy to infer wrongly that the patient is confused. To demonstrate the presence of true confusion requires analysis. A normal subject often has perfect insight into his confusional state, not only when this is simply the expression of fatigue, but in states with really abnormal consciousness, in which there is disorientation. Men who have experimented on themselves with intoxicants or when in hypnagogic states should be able to analyze confusional states in themselves because the incoherence encountered, the confusion of space, time, identity, etc., are of the kind seen in the confusion of soldiers.

In a case cited an officer had forgotten the name of one of his children and of the mayor of his town. This could hardly have been due to mere fatigue or torpor. Several men analyzed together showed the same troubles. They had lost all sentiment, all their affects, save a vague inquietude. They were unable to find their way in a small village with which they should have been familiar. They could not write home because the words would not present themselves. The head felt empty as if from an abrupt arrest of psychic activity. At intervals the confusion lifted slightly. It seemed however that the reawakened faculties immediately became fatigued again.

Considerable difference was seen according to the previous status. Men of low culture and devoid of imagination presented chiefly torpor, mental inertia, mutism, and a general absence of psychic reactions. Such individuals merely vegetate. After recovery the men complained of having suffered fearful nightmares, nights being the time apparently for subconscious activity, although the condition was prolonged into the day. Nothing was visualized, so that the fear inspired seemed unmotivated. The activity was akin to that of somnambulism and of the sort which may cause psychomotor behavior like tics.

The mode of regaining equilibrium throws light on the nature of the confusion. Apparently the critical or synthetic faculty is gradually recovered, so that incoherence becomes abolished. The first faculty to suffer appears to be attention and it is well known that this faculty is the first to suffer in fatigue. The author sees no absolute distinction between primary confusion, so to speak, and that which depends on severe fatigue or intoxication, and other writers on war psychiatry have said the same. Nevertheless, in the psychic fatigue of neurasthenia we do not expect to see actual confusion. The confusional soldier also has points in common with the psychasthenic or hysterical.

In essential confusion there may be a true disturbance of personality in association with amnesia. There is no actual duplication, but the subject behaves somewhat like one in delirium, in which he describes happenings which never occurred to him. The repetition of imaginary events is somewhat stereotyped. He deals with false memories, fantastic visions, in which there is more or less unconscious symbolism. In other words, in true confusion the true and false may be hopelessly jumbled, while in this dream state the subject is quite suggestible, or would be were it not for the degree of incoherence which naturally antagonizes suggestibility. The state of apprehension already mentioned as the only conscious feeling of intensity may exceptionally lead to impulsive acts or to a paraphobia.

In summing up, this type of confusion, while clearly the outgrowth of fatigue, is not related to other well-known results of that condition. Fatigue, for some reason, is expressed by disturbances of consciousness and memory—as if, contrary to other fatigue states, only the highest functions suffer as a result of some selective action on the cortex, a central fatigue. As a result of the inhibitions the subconscious activities assert themselves in the form of a dream existence with incidental psychomotor states.

Reconstruction of Disabled Soldiers in General Military Hospitals.—The War Department announces completion of plans for the physical reconstruction of disabled soldiers in the general military hospitals. These plans have been formulated with a view to close cooperation with the War Department committee on education and special service in the work of restoring men to full or limited military service, and with the Federal Board for Vocational Education. The records of 516 cases treated in four hospitals show 134 men able to return to full military duty, 210 fit for limited service, and 172 who are eligible for discharge. In the last group 121 are able to return to their former occupations. The policy to be followed is that hereafter no member of the military service disabled in line of duty, even though not expected to return to duty, will be discharged from service until he shall have attained as complete recovery as may be expected. The teachers for the work have been secured from among the convalescent disabled soldiers, who are already skilled in their vocations, and from the enlisted personnel of the army secured by transfer or by induction of registrants disqualified for general military service but qualified for special limited service. These instructors work under educational officers chosen for their professional standing in civil life, and commissioned in the Sanitary Corps of the Medical Department; commissions have just been authorized for 119 educational officers. The hospitals designated for reconstruction work are General Hospitals Nos. 2, 3, 4, 6, 7, 8, 9, 11, 16, 17; the Walter Reed, Letterman and Fort Bayard General Hospitals, the United States Army Hospital at Des Moines, Iowa, and the Plattsburg Barracks Hospital at Plattsburg, N. Y.

Reconstruction of Disabled American Soldiers Abroad.—The Department of Labor of the Bureau of Labor Statistics describes the plans that have been developed abroad for the care of disabled soldiers. The American authorities have decided to provide hospital care and treatment and training in England, France, or Italy, for every wounded American soldier whose disabilities are of such a character that there is even a remote possibility of his being in a reasonable time restored to active service on the firing line or retained so that he may take one of the positions behind the lines, thus releasing for the front some physically fit man. Only the men who can give no further military service, or who will require a long course of treatment, will be sent to America. At the Roehampton Hospital, England, 46 per cent. of the men fitted with artificial limbs have been returned to their old trade or business. The British minister of labor reports that about 60 per cent. of the men crippled in the army have been reinstated in their original employment.

Riviera Hospitals for American Wounded.—Extensive hospital arrangements have been made for American soldiers during the coming winter on the French Riviera. Accommodations for 25,000 men have been provided, there being 4,000 beds at Cannes. A plan for taking over several large hotels at Nice is under consideration.

Chateau Near Paris for Wounded Aviators.—Mrs. William E. Corey has given her French home, the Chateau Villeggenisse, near Paris, to the American Red Cross, as a convalescent home for wounded American aviators.

New Way of Amusing Wounded Soldiers.—The National War Work Council of the Y. M. C. A. has solved the problem of how to entertain wounded soldiers who are unable to sit up in bed. Portable motion-picture machines are so stationed at the base hospitals in the camps that the projections appear on the ceiling, and all the patient need do is to look up.

Killed by Shell Concussion.—A cablegram received by the National War Work Council of the Y. M. C. A. reports that the Rev. Walter Murray of East Orange, N. J., met an unusual death while serving soldiers at a canteen near the front-line trenches. He was between two shells that exploded simultaneously, the concussion killing him, although there was not a mark on his body.

Ten Years' Imprisonment for Shamming.—Because of the attempt to evade military duty by feigning insanity, a private at Camp Dix was sentenced by the camp courtmartial to twenty years' imprisonment. The term was later reduced to ten years because the soldier has been in the service but a short time.

Physicians May Still Volunteer.—The Secretary of War and the Secretary of the Navy have issued the following statement: "Orders issued by the War and Navy Departments suspending further volunteering and the receipt of the recruits for officers' training camps from civil life do not apply to enrollment of physicians in the Medical Reserve Corps of the army and in the reserve force of the navy. It is the desire of both departments that the enrollment of physicians should proceed as rapidly as before, that the needs of both services may be effectively met."

Women Doctors Needed in France.—A cable message has been received at the New York headquarters of the American Women's Hospitals, 637 Madison Avenue, stating that there is urgent need for more doctors and nurses to meet greatly increased demands. The hospital for which the doctors are wanted has 25 beds for military and 25 for civilian patients, and is establishing dispensaries in cooperation with the American Committee for Devastated France in near-by towns and villages.

Military Rank for Nurses.—Mrs. Helen Hoy Greeley, counsel for the Committee to Secure Rank for Nurses, announces that a grade above sergeant has been given to army nurses and confirmed by General March, though this announcement has not been made officially. The nurses still feel that this is not sufficient to effect the end for which they are working, namely, the same authority in military hospitals which they would have in the civil hospitals in ordinary times. Following the example of Canada, the Australian army nurses have been given the rank of major, captain, first and second lieutenants, and that is what the American nurses are asking. The highest rank is for the superintendent of the Army Nurses' Corps, the relative rank of major; for the assistant superintendents, directors, and assistant directors, that of captain; for chief nurses and other nurses respectively, the ranks of first and second lieutenant. The grade just ahead of sergeant, which has been given to the nurses places them below the men studying in the camps. A bill embodying these demands is being prepared for presentation to Congress.

The Volunteer Medical Service Corps, which was authorized by the Council of National Defense on January 31, 1918, was reorganized and enlarged on August 5. It will now include not only those who by means of age, sex, or physical disability are ineligible for service in the Medical Reserve Corps of the army or navy, but all legally qualified physicians in the country, whether eligible for service or not, provided they do not already hold commissions in any of the Government services. The plan has received the approval of President Wilson, who, in a letter addressed to Dr. Franklin Martin, chairman of the General Medical Board of the Council of National Defense, says in part:

> I am very happy to give my approval to the plans which you have submitted, both because of the usefulness of the Volunteer Medical Reserve Corps and also because it gives me an opportunity to express to you, and through you to the medical profession, my deep appreciation of the splendid service which the whole profession has rendered to the nation with great enthusiasm from the beginning of the present emergency.
>
> The health of the army and navy, the health of the country at large, is due to the co-operation which the public authorities have had from the medical profession; the spirit of sacrifice and service has been everywhere present, and the record of the mobilization of the many forces of this great Republic will contain no case of readier response or better service than that which the physicians have rendered.

Under the plan of organization the entire medical profession of the country will be classified under four heads: (1) Fit-to-fight men under 40; (2) reserves under 55; (3) home forces over 55; (4) ineligibles. The reserves will consist of those who may be called upon for army, navy, public health, or civilian service when necessity requires. The home forces include those who are able to do only civilian service. The ineligibles are such as have been charged with unprofessional conduct, moral unfitness, or professional inaptitude.

Health of Navy Improved in War.—The death rate in the navy for the week ending August 10 was 1.2 per 1,000 men, a much lower rate than in peace times. This applies to the men both ashore and afloat.

Ambulance Transport Torpedoed.—One of the most harrowing disasters of ruthless submarine warfare occurred on August 3, when the homeward bound ambulance transport *Warilda*, carrying 600 sick and wounded men, was torpedoed and sunk as she was nearing home from France. The torpedo struck in the after part of the engine room, destroying the dynamo and causing the instantaneous death of one hundred patients in a ward just over the dynamo room. The survivors relate heartrending stories of the fearful struggles in the dark to rescue the helpless invalids. There were on board seven Americans, all but one of whom were saved. The loss of life is estimated at from 105 to 130 and upward, and includes several women nurses. More than 650 survivors were landed at a British port.

Lieutenant-Colonel Clarence Leroy Cole, M. C., U. S. A., died suddenly at San Antonio, Tex., on August 9, aged 41 years. He was a graduate of the Kansas Medical College in 1903, and was formerly in charge of the laboratory at the base hospital at Fort Sam Houston.

Ambulances for Women's Service.—The National League for Women's Service has received a gift of four ambulances, valued at $10,250, from the cloak and suit trade. The motor corps of the league is assisting in the removal of the wounded men from the transports, and has now eight ambulances in operation.

A CASE OF SO-CALLED PANCREATIC INFANTILISM.

PANCREATIC infantilism is known to us chiefly through the celebrated case of Byrom Bramwell. A similar one was reported by Rentoul, and if others are on record their number must be very few. In the *Revista de la Asociacion Médica Argentina* for April, Bullrich reports in full detail the following observation: A boy entered the Alvear Hospital in Buenos Ayres with diabetes. The general appearance was one of retarded development. The family history was good and personal history that of the average child—he had had measles, whooping cough, and one unknown malady accompanied by swelling. A photograph taken at the age of nine showed a boy well developed for that age. He was 16 years old when admitted and his failure of health had begun about four years before. He had diabetes and diarrhea; at night there was incontinence of both urine and feces. The abdomen was protuberant. He appears to have had dropsical attacks but was free from edema on admission. His mental processes were normal. The height was 4 ft. 1 in., weight 46.2 lb. The genitals were infantile and there was neither pubic nor axillary hair. The skin was dry and wrinkled and the face senile. The thoracic organs were normal and the tuberculin cutireaction was negative. The Wassermann was also negative and the blood count showed absence of anemia. The diagnosis of pancreatic diabetes was evident. The feces contained much fat. Tests with the sound showed diminished trypsin in the duodenal contents.

The case was entirely refractory to treatment and death took place from cerebral complications which apparently had no dependence on acidosis and coma. Autopsy showed normal thoracic organs. The pancreas was small and without lobulation, weighing 60 gms. The abdominal viscera were also normal with this exception; there was nothing to account for the protuberant abdomen, which was evidently due to meteorism. The kidneys and adrenals were quite normal. The thyroid was very small. Upon opening the cranium the cerebrospinal fluid was found hemorrhagic without clot formation. The choroid membrane and other portions of the meninges showed intense congestion and the cause of death had clearly been meningeal hemorrhage. The hypophysis was normal to the naked eye. To the microscope the anterior lobe appeared to have been the seat of a proliferative process which had caused destruction of the normal elements. Microscopic sections of the thyroid also showed anomalies suggesting defective development. The liver was the seat of histological alterations of various types, affecting both connective tissue and parenchyma, which in general resembled those of the pancreas and were doubtless of the same origin and nature. Similar changes seemed to have occurred in the spleen. The pancreas was the seat of a pericanalicular sclerosis without any changes in the veins; there was no infiltration with embryonal cells, no congestion, no proliferation of canalicular epithelium. There was no sclerosis of the islets of Langerhans but these were few in number and showed much variety in size and shape.

The case was clearly of the same type as that described by Bramwell, but the author objects to the name conferred on the syndrome by that author. While there were indeed symptoms referable to a lesion of the pancreas, the actual condition was pluriglandular, and today it would be classed as a pluriglandular syndrome by all.

MEDICAL DEONTOLOGY IN WAR TIME.

MORSELLI (*Annali di medicina navale e coloniale*, January-February) refers to the duty of the Italian practitioners, civil as well as military. They must foster moderation, inculcate the need and practicability of reduced diet, favor the use of a vegetarian regimen, protect the regime of the war, combat the use of alcoholics, exercise rigor in regard to medical certificates and evacuations for unfitness. The number of certificates of disability which have accumulated since the entrance of Italy into the war is so vast that, if correct, they would justify the conclusion that the Italians are victims of physical degeneration, organic decadence, and general softness. The proportion of these subjects who are false hypochondriacs, hystericals, and autosuggestives must be immense. The medical man is inclined to sympathize with this class and to hear them with indulgence, especially as the men and their women may be his clients and personal friends. In some cases, of course, his leniency is well founded. Sentiment, however, has no rightful place here. A good opportunity is given to assure one's clients that bad teeth, flabby stomachs, tense nerves, flabby muscles, and fat around the waist line do not necessarily unfit one for military service. It will often enough be apparent that a man with a slight hernia is not debarred thereby from riding a bicycle, nor another with short sight from being a moving picture patron.

In sanitary services of all kinds will be found many men who have not been severely wounded, but are interned for various more or less trivial

ailments. These subjects do not wish to get well and return to the ranks and their continued sojourn in the institutions keeps out genuine invalids who would be glad to recover as well as slightly wounded who need brief institutional care. All subjects who are really cured or have endurable ailments or are false hypochondriacs should be turned back to the ranks incontinently. Those who present something to work on should be examined thoroughly and promptly cured. In this class with objective finds will be many malingerers, and the medical man must know how to unmask the alleged mutes, deaf and blind, paretics, etc., some of whom are, of course, innocent victims of neuroses.

Under the head of regimen the duty of the medical man is to prevent waste of food while seeing that each man receives the ration which his system requires. Overconsumption must be prevented, and many men who are able to consume 4,000 or 5,000 daily calories can obtain sufficient for their needs from 3,000 or less. Poorly nourished subjects who need building up, and convalescents, may for the time being require more. Many civilians of both sexes can subsist readily on 2,000 daily calories. In regard to variety of ailment the old Roman progenitors of the Italians resembled the natives of the Orient and tropics in their ability to subsist chiefly on cereals and fruits. Animal protein in sufficient quantity can be obtained from cheese with a very little meat, and the legumes supply plenty of dietetic albumin. The medical man must give his full countenance to the use of war breads, etc., and uphold the government in all wholesale attempts to conserve food, despite the fact that it would be both natural and easy to grumble against the rationing of sugar and other comforts. The opportunity should be improved of fighting the tendency to drink alcoholics. In Italy a crusade against the moderate use of wine would hardly be advisable, but excess in wine drinking and the use of stronger alcoholic drinks should be condemned. The medical men are also altogether too indifferent about the excessive use of tobacco, which is beginning to be a very serious problem.

MILK AND VEGETABLES IN THE DIET.

In order that the fighters may be properly fed, economy and a certain amount of self-sacrifice must be practised by the civilian population. Views as to diet must be changed and adapted to meet the new situation. The population must be reeducated, in fact, as to the comparative food value of certain articles of diet. The man in the street must be instructed as to the scientific aspect of food, and many of his long-held ideas in this direction must be overthrown.

The winning of the war rests with the population at large, for if its members do not loyally support the soldiers the results cannot but be disastrous. In the first instance, then, the civil inhabitants of the country have to be taught the value of different foods, so that they may be able to exercise a wise and discriminating economy, and who shall teach them but the medical men.

Many foods easily grown or raised and therefore cheap are as nutritious as the foods difficult to grow or raise and consequently expensive. These facts are not generally known, nor, what is even more essential, is their supreme importance recognized. A campaign of education with regard to food has been inaugurated and it must be conducted strenuously throughout the country both by written and spoken word.

In a special number of *American Medicine* for June, 1918, in which the food problem is dealt with from various viewpoints, Professor H. C. Sherman of Columbia University discusses the place of milk and vegetables in the diet. He points out that milk is the one article of diet whose sole function in nature is to serve as a food, and it is the one food for which there is no satisfactory substitute. Moreover, even from the standpoint of the ordinary conception of food value, it is inherently much more economical of resources to feed farm crops to milch cows than to animals which are raised merely for slaughter, and consistently with this it is usually found that milk is a cheaper source of protein and calories to the consumer than is meat, unless some special marketing or other condition intervenes to interfere with normal economic relationships. Sherman demonstrates that from the broader view of food values, it must be concluded that a quart of milk is a greater food asset than an amount of meat which should furnish the same weight of protein and the same number of calories, and he gives a number of indisputable reasons in support of the validity of the argument. Further, he quotes McCollum to show that milk is the most efficient food in supplementing a grain diet because of its richness in calcium and in fat soluble A. Added to this is the further advantage that the milk proteins supplement in an important way the proteins of the grains and other seeds, especially in those cases in which the requirements of growth, reproduction, and lactation are concerned. In the opinion of Sherman, it has been proved that milk is much more than a substitute for meat, in fact, it has been shown that meat is a very inadequate substitute for milk. Thus not only does patriotism demand the consumption of less meat and more milk, but such a procedure is plainly desirable from the standpoint of our present knowledge of nutrition.

Over and above wheat saving, the food-conservation campaign is essentially an effort to diminish the consumption of meats, fats, and sugars, by substitution of perishable foods such as milk, eggs, vegetables, and fruit. Patriotism carried in this direction will greatly aid in winning the war by ensuring a sufficient supply of food for the fighters and will also act in the interests of public health and of economy. The substitution, to a great extent, of milk and vegetables for meat and wheat, will, ac-

cording to Sherman, result in the better support of growth and reproduction, the maintenance of a better hygiene of the intestine and higher reserve alkalinity of the blood, and the safeguarding of the body against any tendency in the direction of the so-called deficiency diseases.

Truths of this kind should be instilled into the minds of the community, for when it is thoroughly understood that it is patriotic as well as cheaper and more beneficial to health to subsist upon milk and vegetables, rather than upon meat and wheat, the merits of the former combination cannot but prove irresistible.

Rickets in Relationship to Housing.

The favorite theory of the causation of rickets is that it is due, or mainly due, to errors of diet; to the administration of food, for instance, lacking in the vitamine element. However, this view is not universal. Dr. Leonard Findlay, writing in the *Glasgow Medical Journal* for May, 1918, does not believe that dietetic errors are responsible for the causation of rickets. Experiments made by himself and others appear to show that diet plays an insignificant part in the causation of the condition. He is of the opinion that the following are the causes of rickets in the order of their significance: (1) Improper housing. (2) Absence of facilities for open air life. (3) Imperfect parental care. Poverty *per se* does not seem to be of any importance, and Findlay asserts that investigations show the conclusion is warranted that diet has no bearing on the etiology of rickets. Findlay has demonstrated to his own complete satisfaction that the frequency of rickets is directly proportionate to the air space in the home available per person. Furthermore, lack of exercise in the open air, he says, is a contributory factor of great consequence in the causation of the disease.

The Alimentary Chemistry of the Boche.

Dr. Matignon states in the *Journal de Médecine de Bordeaux* for May that the German chemists have striven valiantly against the results of the blockade; whenever the Allies shut off a new portion of the ration these men are right there with new substitutes. One almost thinks, says the Frenchman, of the miracles of the New Testament. In the *Vossische Zeitung* a professor in the Berlin University has expressed himself as follows: "It is useless to conceal the truth longer. The Government must supervise the flood of substitutes which threatens to engulf us. Otherwise the end of the war will see an end of one-third of the German people. Besides, the other remaining two-thirds will be so debilitated by undernourishment that they will have neither strength nor means to recuperate themselves. Only the devil knows what these substitutes contain or what the people eat in place of butter, eggs, cheese, oil, meat, milk, soup, coffee, sugar, tobacco, fish, tea, caviar, etc. The very latest finds of the chemists are too rank to be tolerated. Oil for frying is obtained from crude petroleum. To this product alone 800 cases of indisposition and eight deaths have been imputed. Dog fat has been substituted for that of the goose, "eggs" for pastry are composed of a mixture of chalk, flour, and yeast, caviar consists of fish scales, and bread is made of straw." The learned German professor asks how patriotism alone can enable a people to withstand forever such a state of affairs.

The Cosmetic Mask.

In *La Presse Médicale* for May 30 is a brief account of the activities of an American lady, Mrs. Ladd, wife of an American physician in the Toul sector, in the direction of making masks for disfigured soldiers. Born in Boston, she studied sculpture in Paris and Rome. Among her successful works, one, "La Paix Victorieuse," is specially admirable. The slow process of recreating new features in a face become almost unrecognizable influenced her to contrive a cosmetic mask, which serves alike for temporary or permanent use. In this work she is being financed by the American Red Cross, and has derived artistic support from the work of Derwent Wood, the British sculptor. She makes a mold of the face, and from this a face of wax by the aid of old photographs of the victim. This wax face is only a model, the actual false face being made of silver-plated copper, very thin and light. The features of the subject are then reproduced on the mask in oil colors, the eyebrows and moustache being, of course, of false hair. Two photographs accompanying this article, of terribly disfigured soldiers, show fine cosmetic results, which are naturally, however, not intended or expected to deceive any one. Doubtless, with dim illumination, or at a reasonable distance, deception might result, but the benefits are wholly moral. The victim can feel at ease, his relatives are spared much mental anguish, and the public escape a harrowing spectacle. The mask is to be worn chiefly on the public streets and in the public conveyances, and the illusion of reality is at times really very marked. The models and masks, so carefully prepared, may serve the plastic surgeon as a guide if the features are to be reconstructed.

News of the Week.

Cholera Spreads Unchecked in Petrograd.—A despatch from Amsterdam states that there have been more than 20,000 cases of cholera in Petrograd up to August 6, and that up to August 3 there were 1,100 deaths. It is said that the authorities are helpless to check the spread of the disease, and that the epidemic is not expected to cease until all the available material for the disease to work upon is exhausted.

Yellow Fever in Guatemala.—Yellow fever is reported to be raging in Guatemala. The average number of deaths from the disease is said to be about 40 daily.

Red Cross Needs Doctors.—The New York Chapter of Red Cross has issued a call for additional physicians to offer their services in providing free medical service to the families of soldiers and sailors. This work is being carried on from the Red Cross Medical Station at 314 East Fifteenth Street, Manhattan. According to the announcement from the Red Cross the number of cases to

be treated is rapidly increasing while the number of physicians volunteering their services is decreasing. In order to continue the work the services of additional physicians are badly needed.

A Memorial to the Late Dr. Trudeau.—A statue of the late Dr. Edward L. Trudeau was unveiled at the Trudeau Sanatorium, at Saranac Lake, on Saturday, August 10. Dr. Francis B. Trudeau unveiled the statue, and addresses were made by Dr. Walter B. James and Miss Louise Bonney.

Ambulance Wrecked.—As the result of a collision between a Coney Island Hospital ambulance and an automobile on Ocean Parkway, Brooklyn, the ambulance was completely wrecked and its occupants cut and contused.

Doctors Increase Fees.—The physicians of Webster, Mass., have increased their fees. Henceforth, house calls between the hours of 7 A. M. and 7 P. M. will be $2, within a certain radius. Within a larger radius they will be $3, and within a still wider radius $4. Confinement cases will be $10 up, according to the time spent and the operation performed. For all calls between 7 P. M. and 7 A. M. an additional dollar will be charged.

Hospital Annex Burned.—The frame annex of the Rahway (N. J.) Hospital was damaged by fire to the extent of $5,000 on the night of August 3. No one was injured.

Dr. Timothy D. Lehare, for fifteen years a coroner's physician of New York City, has been appointed police surgeon for the Thirteenth and Fourteenth Districts.

Dr. Julius P. Brown, recently tried on charges of neglect of duty by the Hylan administration, and acquitted, has been unanimously reinstated as director of the Bureau of Food and Drugs of the New York Board of Health. In acquitting him of blame the board publishes an implied censure of the administration of the two health commissioners who served before Dr. Amster.

Deaths of Foreign Medical Men.—Dr. JOHAN WILHELM RUNEBERG, who was perhaps the foremost medical figure in Finland, died last May at the age of 75 years. In addition to general practice he did surgical work and conducted laboratory researches in physiology. The first subject with which he identified himself was albuminuria, and his first research was conducted in the laboratory of Leipzig University. He maintained his interest in this subject, and was regarded as an authority on Bright's disease. He developed his own classification of the varieties of nephritis, and differentiated carefully between inflammatory and degenerative forms. He made an exhaustive study of the albumin content of ascites cases and studied 164 cases with this end in view. Another subject which he had studied with great care was anemia, with special reference to pernicious forms and parasitic anemias. A third subject on which he was an authority was arteriosclerosis. As a surgeon he was one of the very first to develop the surgical relief of pulmonary abscess and gangrene. He was also an extensive early operator on empyema, and was therefore entitled to rank as one of the pioneers among thoracic surgeons.

Dr. LEOPOLD MEYER of Copenhagen died recently at the age of 65 years. He was distinguished as an obstetrician and gynecologist. He published a monograph on the pathology of pregnancy in 1906 and a textbook on midwifery in 1914. He was an authority on obstetrical operations as well as abdominal surgery.
